THE DOMINIONS HOSPITALITY COMMITTEE.—The Dominions Hospitality Committee, announced last week as in process of formation, is now nearly complete. The purpose of the Committee is to offer welcome and to extend hospitality to all British medical men visiting London during the Empire Exhibition this year. The following have consented to serve on the Committee:—President: Sir William Hale-White (President of the Royal Society of Medicine). Vice-President: Sir Bruce Bruce-Porter (President of the Hunterian Society). Sir Humphry Rolleston (President of the Royal College of Physicians); Mr. H. J. Waring (Vice-Chancellor, University of London; Vice-President of the Royal College of Surgeons); Surgeon Vice-Admiral J. Chambers, R.N. (Medical Director-General, Navy); Maj.-Gen. Sir William Leishman (Director-General, A.M.S.); Air Commodore D. E. Munro (R.A.F.); Mr. C. P. Childe (President of the British Medical Association); Dr. Herbert Spencer (President of the Medical Society of London); Sir William Willcox (President of the West London Medico-Chirurgical Society); Dr. Dudfield (President of the Harveian Society); Dr. Crewdson Thomas (President of the Chelsea Clinical Society); Mr. J. Cunning (President of the Australian and New Zealand Medical Society in England); Mr. Donald Armour (Canada); Dr. H. A. Ellis (Australia); Sir John MacAlister (Secretary, Royal Society of Medicine); Sir Squire Sprigge (Editor of THE LANCET). Hon. Secretaries: Mr. A. E. Mortimer Woolf (Hon. Sec., Hunterian Society); Mr. E. T. Milligan, O.B.E. (Hon. Sec., Australian and New Zealand Society in England). The address of the hon. secretaries for all correspondence is 1, Wimpole-street, London, W. 1.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXI.

THE TREATMENT OF MALARIA AS MET WITH IN ENGLISH PRACTICE.

THERE are three forms of malaria, which, though possessing several cardinal features in common, are caused by three distinct parasites—the benign tertian, the quartan, and the subtertian (sometimes also known as the malignant). The clinical symptoms produced by these three parasites vary very considerably, and it may be said that, though the pathology and treatment of the two first-named varieties are similar, that of the subtertian differs very considerably. The clinical states produced by malaria which may be encountered in English practice are due either to benign or subtertian parasites. It is therefore important to realise that the term "benign" as used in this sense is in many ways a misnomer, for, though not actually dangerous to life itself, the benign parasite may cause considerable disability, and, owing to its proclivity to relapse, it is much less amenable to quinine therapy than is the subtertian.

Diagnosis.

The diagnosis of the main forms of malaria rests upon the detection of the parasite in the blood by means of the microscope. There are certain definite morphological features by which the parasites may be distinguished in stained blood films, but difficulty may be experienced in differentiating the youngest or ring forms of parasite which are found in the blood during the course of a febrile attack.

There is a widespread idea which appears to rest upon inadequate foundations that the parasites of malaria appear in the blood-stream in sufficient numbers to be recognised under the microscope only during the febrile paroxysms, but this is by no means the case. It is true that they are the more readily demonstrable, but they are present also during the apyrexial periods when the immature forms of the parasite can be found, if the films are searched thoroughly by a skilled microscopist. In the physical examination of malaria one may be guided by the anæmia so often associated with the disease, as well as by the splenic enlargement, but neither of these (which are usually considered cardinal signs) may be present. Obvious anæmia may be altogether absent in the pernicious attacks of the subtertian infection which are so dangerous to life, nor may the spleen be palpable. The absence of these two signs should not prevent one from examining the blood, which constitutes the only absolute guide to diagnosis.

The symptoms of benign tertian malaria are generally sufficiently obvious in the acute stage; the fever it evokes is sudden, severe, and of short duration; it is accompanied by the usual phenomena of rigor and sweating, but there are other cases in which a pyrexial attack does not develop; the patient may then experience a transient malaise, slight shiverings, or headache. As a general rule, it is the latency of the benign parasite and its liability to recrudesce at any period—it may be for four years—from the time of the original infection, which renders it such a particularly annoying and disabling disease. Months may pass between particular attacks, but after undue exertion or exposure to cold the patient may be struck down again by fever.

The symptoms of the subtertian infection are entirely different. As a general rule, the clinical symptoms are more insidious in their onset, the attack of longer duration, of less dramatic effect, but considerably more injurious to health. The clinical guises which subtertian malaria may assume are very numerous. It may produce extremely acute pernicious symptoms and death within a very few hours. Again, the symptoms may be mainly nervous in origin,

eventuating in mania, delirium, coma, and even epileptiform convulsions; they may be abdominal—dysenteriform or choleraic. There may be no pyrexia at all, the patient may complain of loss of appetite, nausea, and dyspepsia; yet such an individual is liable at any moment to the onset of a sudden pernici us attack, or, it may be, to the supervention of blackwater fever, which is now recognised as a complication of this form of malaria. The blood of individuals returning from the tropics, whatever their complaint may be, should invariably be examined for the subtertian parasite, and should it be found, the case should be regarded in a serious aspect and the infection as a potential danger to life itself.

Treatment.

There is only one specific drug in the treatment of malaria, and that is quinine. Considerable doubt has been cast upon this question during and since the war, mainly occasioned by the failure of quinine therapy to prevent relapses in the benign tertian infections. No drug is absolutely specific, and any hesitation which may have arisen on this point has its origin in failure to appreciate the limitations of quinine therapy.

As soon as a diagnosis has been arrived at, quinine should be given, and it must be exhibited in such a manner that it can be absorbed, and, moreover, it must be continued over a considerable period of time. Whenever possible quinine should be given by the mouth, and only in cases of persistent vomiting or in the severe or pernicious forms of the disease should the drug be injected.

Benign Tertian.—As soon as the patient commences to perspire quinine should be given in solution in 10 gr. doses three times a day after food. The sulphate and the hydrochloride are the two salts of quinine most frequently prescribed, the latter, being more soluble, is preferable. It may be given as follows:

Quinine hydrochlor.	gr. x.
Acid. hydrobrom. dil.	℥ ii.
Syr. aurant.	drm. i.
Aq. chloroformi	ad ½ oz.

The addition of the hydrobromic acid is designed to assist in the solution of the quinine, and has the reputation of preventing the disagreeable tinnitus which results from the absorption of the drug. In the case of an adult this dosage of quinine should be persisted in for the next week and in all probability the succeeding attacks will be thereby prevented, but thereafter, with a view to preventing the recurrence of fever, the patient should persist in quinine therapy for some considerable time. It is usual to reduce the quinine to 20 gr. a day in the second week, and subsequently to 10 gr. a day for the next two and a half months; this is what is generally termed anti-relapse treatment. The only sound method hitherto devised to effect this purpose is the regular and constant exhibition of small doses of quinine over a long period. Should this be neglected the parasite will most certainly recrudesce and numerous relapses result.

Quinine sulphate in pill form as a means of curing malaria or preventing relapses should be avoided. Quinine is only readily absorbed when the intestinal tract is in a healthy condition, therefore it is necessary that the patient should take a mild saline such as sod. sulph. oz. i. once or twice a week while on quinine therapy.

As adjuvant to quinine in the acute fever the following diaphoretic mixture may be given:—

Liq. ammon. acet.	drm. ii.
Spir. æther. nitros.	℥ xxx.
Aq. camph. co.	ad ½ oz.

Arsenic has the reputation of acting as an adjuvant to quinine, and at the same time it assists in combating the anæmia. It is customary, therefore, to prescribe the following mixture to be taken in addition to the quinine, to be taken twice daily:—

Acid. sol. arsenic.	℥ iii.
Ferrous sulph.	gr. ii.
Acid. hydrochlor. dil.	℥ iii.
Aq. ad	½ oz.

There are many preparations of quinine, the most insoluble, such as euquinine and quinine tannate, are tasteless, so their value in the treatment of the disease is doubtful. Cinchona febrifuge, a preparation much used in India, contains the additional alkaloids of cinchona bark, and is given in the same doses as quinine and acts much in the same manner. Esanofele, a proprietary drug much used at present, contains quinine bisulphate and arsenious acid. To some people the bitter taste of quinine is intolerable; to such the hydrochloride may be given in powder form in cachets, or the patient may be directed to drink milk or chew bread immediately after the dose of quinine, both of which methods assist in removing the obnoxious taste.

Salvarsan and its derivatives are considered by some authorities to exert a parasiticidal effect in malaria; it is extremely doubtful whether this is true. Undoubtedly, when used in combination with quinine and given in small doses (0·3 g.) as intravenous injections once or twice a week, they exert a distinct stimulating effect and are thereby useful in the anti-relapse treatment of the benign tertian infection.

Subtertian.—The treatment of cases of average severity is on the same lines as that already described. The patients are usually men who have recently returned, apparently in good health, from the West Coast of Africa or other endemic focus of this infection, who may give no history of fever whatsoever, but in whom suggestive symptoms may appear on arrival in England. The subtertian parasite responds quickly to quinine treatment, and as a rule does not relapse; on the whole, therefore, the treatment of this form is much the more satisfactory.

Should the parasites be very numerous in the blood-stream and the clinical symptoms of the patient very severe, quinine should be injected intramuscularly. For this purpose the bi-hydrochloride salt is chosen. It should be injected in solution deep into the substance of the gluteus maximus in 7 to 10 gr. doses. As a general rule, one or two injections are sufficient; more numerous ones, or those containing larger doses of quinine, are much to be deprecated. Quinine is a tissue poison and may cause extensive necrosis, and, moreover, the danger of "blackwater fever" supervening must not be overlooked, for there is a certain amount of evidence for the view that an injection of quinine may precipitate a hæmolysis of the blood cells and thereby bring about hæmoglobinuria. Intravenous injections of quinine are rarely necessary, save in the comatose or cerebral types. In this case 10 gr. of quinine bi-hydrochloride should be injected intravenously in 10 c.cm. of distilled water by means of a record syringe.

Medicine and the Law.

HARNETT v. BOND AND ADAM.

AFTER a trial lasting 16 days before Mr. Justice Lush, a special jury found answers to a series of questions and awarded damages in an action brought by Mr. W. S. Harnett against Dr. C. H. Bond, a Commissioner in Lunacy, and Dr. G. H. Adam, manager of a home for the reception of insane persons at Malling Place, Kent. Damages were claimed on the ground of the alleged wrongful detention of Mr. Harnett as a lunatic. In 1912 he had been an inmate of Dr. Adam's asylum for a few weeks, and on Dec. 12th was allowed to leave it on probation for 28 days. Two days later he went to the office of the Board of Control, where he had an interview with Dr. Bond, who, after conversation with him, detained him and communicated with Dr. Adam by telephone. As a consequence Mr. Harnett was taken back that afternoon to Malling Place in a motor-car by two attendants sent for him by Dr. Adam, after which he was kept there and in other asylums till Oct. 15th, 1921, on which date he escaped, and was afterwards certified as sane by the mental specialists whom he consulted.

A summary of the evidence, speeches, and summing-up follows; the findings of the jury at the conclusion are given here in order that the precise issues raised by the specific points submitted to them may be appreciated.

1. Did Dr. Bond cause the plaintiff to be detained at the office until the attendants came for him?—Yes.

2. Did he cause him to be sent back for the purpose only of his being examined by Dr. Adam or for the purpose of his being detained at Malling Place?—Being detained at Malling Place.

3. Did Dr. Bond cause the plaintiff to be taken back?—Yes.

Did he and Dr. Adam agree, after consultation, that the plaintiff should be sent for and taken back?—No.

Was the taking back entirely the act of Dr. Adam?—No.

4. Was the plaintiff of unsound mind on Dec. 14th, 1912?—No.

Was he fit to be at large?—Yes.

Was he dangerous to himself or to others?—No.

5. Did Dr. Bond honestly believe that the plaintiff was of unsound mind, not fit to be at large, and dangerous to others?—No.

6. Did he believe that the plaintiff had escaped from his brother's charge; and, if so, was that his reason for having him sent back?—Yes.

7. Did he take reasonable care to ascertain the true facts?—No.

8. Did he honestly believe that Dr. Adam had retained the power of retaking the plaintiff back during his 28 days' leave of absence?—Yes.

9. Did Dr. Adam, when he received the telephone message and sent his car, honestly believe that the plaintiff, on Dec. 14th, 1912, was of unsound mind and unfit to be at large?—Yes.

10. Did he honestly believe that it was in the plaintiff's interest that he should be taken back to Malling Place?—Yes.

11. Did he take reasonable care in doing what he did?—No.

12. Did he make it known to the plaintiff that he was liable to be taken if his mental condition required it?—No.

13. Was the detention of the plaintiff at the Commissioners' Office the act of Dr. Bond alone, or was it really the act of both defendants?—Dr. Bond.

The jury assessed the damages at £25,000, apportioned as follows: £17,500 against Dr. Bond, £7500 against Dr. Adam, subject to reduction if it were held that there was responsibility only for the plaintiff's detention by Dr. Adam, to £10,000 (Dr. Bond £7500, Dr. Adam £2500), and alternatively £5000 against Dr. Bond in respect of the detention of the plaintiff at the offices of the Commissioners in Lunacy. The judgment given two days later after argument by counsel will be found below.

Mr. J. B. Matthews, K.C., opening the case for the plaintiff, declared that there was no right whatever on the part of Dr. Bond, any more than there was for any citizen, to detain anyone or give him into custody as a lunatic. The plaintiff had originally been put under restraint upon certificates given by Dr. H. Fisher and Dr. Penfold (since dead) under a reception order signed by a justice of the peace, and an action was pending against Dr. Fisher. The grounds for the first certificate were detailed by counsel. Mr. Harnett, after the death of his first wife in 1908, had believed himself infected with nasal catarrh through germs contracted from her, and an unqualified person had treated him with injections of tuberculin. As a result he had suffered from fever and delirium, and in October, 1912, had been under the care of male nurses. On Nov. 10th he was certified and received at Malling Place. He was certified as deeply steeped in sex problems, but, said counsel, many people, especially since the war, had taken an interest in sex problems and discussed them openly as they would not have done before. The plaintiff had thought that the young should be instructed in sex matters and had issued a pamphlet dealing with the subject.

Mr. Harnett then gave evidence and described having waited from morning to afternoon at the offices of the Board of Control under the impression that his affairs were being looked into, and said that he had been hindered by a clerk when he wanted to go out to luncheon, and was removed at 2.30 P.M. on Dec. 14th. Further, he complained of rigorous treatment at the asylum. He said that he had escaped from an asylum at Aylsham, Norfolk, after complaining without effect to the Lord Chancellor. A number of letters were read addressed by the plaintiff to the Lord Chancellor and to the Commissioners complaining bitterly of his confinement and of his treatment, and the plaintiff, continuing his evidence, said that he had been kicked and struck by a lunatic, that he had complained to a visitor and been threatened by Dr. Adam for doing so. In cross-examination, he said that since Oct. 31st, 1912, he had been perfectly sane. He had never seen any vision or heard supernatural voices since seeing his mother's spirit in 1896. In November, 1912, when ill, he had said, "You people think I am mad." "They did not answer, and I said, 'Spell parallelogram.' They still did not answer and I spelt it correctly." He suggested that his wife and Dr. Penfold had persuaded his brother to have him confined.

Mr. E. Hambrook, a farmer, Mr. A. A. Norman, a solicitor, Mrs. M. A. Girdlestone, a relative, Mr. E. Field, who had attended the plaintiff as a dentist, and the Rev. J. W. Jones, who had been in contact with Mr. Harnett before and during his detention in mental homes, were of the opinion that when they saw him he was sane. Dr. H. J. Bryan was consulted by the plaintiff on Dec. 13th, 1912, and only found him "talkative." Dr. J. S. Risien Russell had examined the plaintiff in November, 1921, and certified him as sane. He considered that his re-arrest and sending back to the home was calculated to have a detrimental effect. Dr. A. C. Morton, instructed by the Commissioners, had visited Mr. Harnett in the mental home at Aylsham and became friendly with him. In June, 1921, he had told a Commissioner that if the plaintiff were at liberty he should not certify him. He admitted, in cross-examination by the Attorney-General for Dr. Bond, that he had reported of the plaintiff that he was talkative and excitable, had some religious mania, and seemed under the impression that he was being persecuted. This was in May and June, 1921. He was then on the border line with regard to religious mania, but the witness could not recall what his delusions were. Dr. T. Hyslop examined Mr. Harnett in November, 1921, and found him capable of managing his affairs.

At the close of the plaintiff's case it was submitted that there was no case for damages, that the only case against Dr. Bond arose out of the detention at the Commissioners' Office, and that Dr. Adam in the circumstances could not have acted otherwise, but the judge held that the trial must go on, and said that there was a prima facie case that Dr. Adam had had

the plaintiff brought back without first satisfying himself that he ought not to be at large.

The Attorney-General, Sir Patrick Hastings, K.C., opening the case for Dr. Bond, referred to the difficulty of devising any means by which more complete protection could be given to any individual detained as insane than had been afforded to Mr. Harnett. But he admitted that after the evidence heard that day there were grave doubts whether any satisfactory method could be adopted to ensure that no person hereafter should remain in an asylum without independent investigation. The Attorney-General suggested as the best protection the visits at stated intervals of an independent doctor at the instance of the alleged lunatic or of his friends. He did not say that the plaintiff had not now recovered, but in 1912 he was undoubtedly insane.

Mr. Neilson, K.C., opened the case for Dr. Adam, who, he said, had received the plaintiff when his actions appeared to be entirely uncontrolled. The plaintiff's mother, he added, was insane.

Dr. Bond described the visit of the plaintiff to the offices of the Board and his own interview with him. He had not been able to find out the object of the plaintiff's visit. Mr. Harnett had talked incoherently in broken sentences, and flourished a bag of money which, he said, he had obtained from his bank. After half an hour he formed the opinion that Mr. Harnett was insane and not fit to be about alone, and had told Dr. Adam so by telephone. In cross-examination Dr. Bond was asked with regard to the flourishing of a bag of money, "What more natural or more joyous than that a man should jingle golden sovereigns in a bag?" and his Lordship asked, "You would not call that a proof of insanity?" To which Dr. Bond replied that he should expect a man to keep his money in his pocket. He did not say that Mr. Harnett had not now recovered. He had not examined the plaintiff, who had given his evidence coherently and sensibly, as to his mental state.

Mr. B. R. Dickson, a land agent, Mr. W. Hyder, a solicitor's clerk, and Mr. C. M. Moir, a reporter, gave evidence as to the plaintiff's interviews with them, and as to such acts as grovelling on the floor, asking Mr. Hyder whether he could spell "parallelogram," and describing visions that he claimed to have seen. To the last-named Mr. Harnett had attributed his condition to an overdose of a vaccine. [These witnesses referred to dates before Nov. 10th, 1912, at which date, Mr. Matthews admitted, the plaintiff was rightly certified.]

Mr. A. Harnett, plaintiff's brother, also spoke to his conduct in that period; he had not visited the plaintiff in confinement, having heard that the plaintiff had threatened revenge against him for putting him under restraint. The plaintiff had said he would spend his last penny in punishing all those who had taken part in putting him away.

Dr. Adam stated that he had joined his father in managing the mental home at Malling Place in 1907, and since his father's death in 1908 had managed it alone. He had received Mr. Harnett on his certification and then thought him maniacal, but had sent him out when his condition improved on an order in the usual form with a proviso for power to take him back should his condition require it. In February, 1913, after his return, he had reported to the Commissioners that the patient was not suicidal but inclined to be dangerous and likely to elude a single attendant. Cross-examined as to various acts of the plaintiff and in each case as to whether the act indicated or proved insanity, the witness answered in the negative, with qualifications, saying that all the facts taken together would be evidence of insanity. The acts referred to included addressing friends and neighbours, asking them to testify to his sanity, claiming a mission to go out and "save souls," asking the Governor of Borstal Prison for leave to address the prisoners, writing a letter to "Dear Postal Official" beginning "Jesus has touched my eyes," and talking incoherently and ramblingly on religious subjects. Mr. Matthews, with regard to the way the plaintiff talked, said, "Everyone from preachers to race-course touts raises his voice to emphasise what he says." The witness answered, "He was shouting, and, in my opinion, was suffering from mania." The witness had reported him later to be "Mentally improved, the acute attack of religious mania having passed off"; the condition then was that religious symptoms remained and "his mind was more or less monopolised by religion." He considered that if the plaintiff believed he had a tuberculous throat after he had been told by a specialist that he had not, that would be a delusion, while he had added that he also thought he had cancer of the throat. He had expressed a desire to go and live with Lord Wolseley. It was suggested by counsel that the plaintiff said: "I should like to see Lord Wolseley to shake hands with him and say 'Lord Wolseley, your sword is untarnished.'" The witness did not remember this, but admitted that an explanation might be found in both the plaintiff and Lord Wolseley believing in the efficacy of prayer.

Dr. H. Fisher gave evidence as to having seen the plaintiff on Nov. 9th, 1912, and having certified him as of unsound mind. Cross-examined as to the symptoms connected with religion, and having said that the people living with the patient were not the best judges of his state, he was asked, "So it is the doctor who is to be the ultimate judge," and replied, "I am afraid we are often drawn into this kind of thing against our will." The plaintiff's actions most certainly indicated insanity. Asked by the judge what made a man a lunatic, he answered, "Laying undue emphasis on circumstances which in ordinary life would be of no moment." The offer to preach to Borstal prisoners should be taken in conjunction with other matters. The required examination of a patient did not necessarily involve asking questions, the word used being "observe." He had gone to the examination with a perfectly open mind.

A former head attendant at Malling Place described bringing the plaintiff back from the offices of the Board, and said that he then appeared worse than when he left. He had not been treated badly or threatened.

Dr. T. Claye Shaw, visiting physician at Malling Place, deposed to having had an interview with Mr. Harnett there on Nov. 19th, 1912, and having had no doubt of his insanity, and as to a delusion with regard to a plot against him. He said that excitement in relation to insanity was a question of the degree of excitement shown. He was cross-examined generally as to his experience of the correctness of certification in other cases within his experience.

Dr. Ludford Cooper had been called in by Dr. Penfold to see the plaintiff in October, 1912. While the plaintiff was out on probation in December, 1912, he had found him outside his house and had asked him into his consulting-room. Arrived there, Mr. Harnett had at once fallen on his knees and prayed aloud, following him across the room still kneeling. Beyond the words "Jesus Christ" he was incoherent, and afterwards got up and talked about a plot. The witness had no doubt that he was insane. He had communicated with Mr. Harnett's solicitor and with Dr. Penfold. Later he had met the plaintiff at Malling Place when visiting another patient and Mr. Harnett had shaken him cordially by the hand and asked him "How do you spell parallelogram?"

At this point Dr. Fisher was recalled and was shown a receipt which he acknowledged had been given by him for fees for attendance on Mrs. Harnett, the plaintiff's wife. He had made a statement under cross-examination to the effect that if Mr. Harnett had said that he (the witness) had ever attended Mrs. Harnett, he would have treated it as a delusion. He now withdrew that statement, and was severely censured by the judge, who characterised the evidence as given to help in establishing the plaintiff's insanity.

Dr. Cooper, further cross-examined, said that the plaintiff had referred to something of a painful and delicate nature affecting his wife, and might have suggested that that was the reason for his being put away. He might have dropped on his knees and in

that position related what was on his mind. The Attorney-General offered to go into the matter affecting Mrs. Harnett by calling her as a witness. He was chiefly concerned with the state of the plaintiff's mind in December, 1912.

His Lordship said that he should ask the jury whether the plaintiff was insane on Dec. 14th.

Dr. A. I. Webster said that on Dec. 13th, 1912, Mr. Harnett, to whom he had never spoken before, called on him, and said excitedly, "Dr. Webster, you are a deeply religious man; you believe in the Lord Jesus Christ." He knew of no reason for this, and considered the plaintiff to be of unsound mind. In cross-examination he admitted having read the lessons in church, of which the plaintiff might be aware. He knew that the plaintiff had been in an asylum.

Mr. O. Dickinson, secretary to the Commissioners in Lunacy, gave an account of the visit of the plaintiff to the Commissioners' offices on Dec. 14th, 1912. He looked wild, seemed excited, and was very talkative. The witness described the removal of the plaintiff. There was no reference to the plaintiff's condition in the memorandum made of the visit, but it was mentioned that he had escaped from his brother's charge. He told the judge, in reply to a question, that he could not account for this. His Lordship said, "I attach the very greatest importance to it."

Dr. E. S. Pasmore said that in 1913 he was medical superintendent at Croydon Mental Hospital, and in February of that year fetched the plaintiff from Malling Place. On the way to Croydon Mr. Harnett, in reply to questions, said he had been poisoned with tuberculin and it went to his head. He voluntarily said that he had a mission to save souls and had supernatural power, but he had been prevented from trying to save Wesleyans' souls and had tried to save souls of those condemned at Borstal. He pooh-poohed the suggestion that boys at Borstal were not condemned to death. He expectorated and explained that this was to rid his system of acid injected into it. Cross-examined, Dr. Pasmore said that in 1913 he reported that the patient suffered from "mental exaltation," and his offering to preach at a Wesleyan Church tended to confirm this, as he was not a Wesleyan. In 1914 he appeared to be threatening violence against those responsible for his detention. The witness denied that to develop homicidal tendencies after two years necessarily pointed to chronic permanent lunacy. The symptoms he referred to had nearly passed away in 1917 when he advised that the plaintiff should stay as a private patient in a doctor's house. The witness thought it true that the plaintiff had offered the Commissioners £30 to send a mental detective to his home, to see that he had fair play, but he had not been able to get from him a statement as to the nature of the foul play he suspected.

Dr. H. M. Berncastle, assistant to Dr. Pasmore, described a conversation with Mr. Harnett at the Croydon Mental Hospital, and said that he claimed a mission to save souls, and the possession of supernatural powers. The plaintiff had resented the witness questioning him. He did not seem to realise that when released from Malling Place in December, 1912, he had been let out on trial, but perhaps explanations now given might have put this in a rather different light. He understood him to threaten violence, not legal proceedings. He had heard him give evidence, and should not even now certify him as of sound mind without making a special personal examination.

Lord Sandhurst described interviews with the plaintiff in July, 1913, May, 1917, March, 1920, and June or July, 1921. At the first, lasting three-quarters of an hour, he had formed the opinion that he was in a state of mental exaltation. Mr. Harnett had attributed his illness to the administration to him of a toxin. He had described graphically his religious attitude. He had not thought it desirable that the plaintiff should manage his own affairs, having made this visit for the information of the Master in Lunacy as to the appointment of a receiver. With regard to a later visit, the witness said that he was not there to inquire into the state of the plaintiff's mind with a view to his release. In 1917 he appeared more composed than in 1913, better still in 1920, and there seemed nothing wrong with him in 1921. Hostility to his wife, apparent in 1920, had disappeared in 1921.

Sir James Crichton-Browne gave evidence as to an interview with the plaintiff at Croydon in his capacity of Visitor in Lunacy in 1913. This was at the plaintiff's request after the visit of Lord Sandhurst in July of that year. Dr. Pasmore was out and the witness had formed an entirely independent opinion, without seeing the original certificates. He was with the plaintiff for three-quarters of an hour and satisfied himself without any doubt that he was of unsound mind and dangerous. He had not seen him before or since. The plaintiff was intelligent and had a good memory at the beginning of the interview, and said that he had been infected with nasal catarrh by his first wife after she had been dead three or four years, and that he had been injected with tuberculin by a tailor. He had received a mission from God to preach to sinners. He had a special mission to preach to boys and girls upon matters relating to sex. Asked whether he meant this as to girls, he said "Yes," and that God had prepared him. He was talkative and voluble and became excited.

The witness was proceeding to give statements of the plaintiff concerning his wife, but counsel on both sides wished to exclude this topic, and Sir James Crichton-Browne, having stated that Mr. Harnett had spoken of a "horrible discovery" a month after marriage, said that he formed the opinion that the whole thing was a delusion. The plaintiff had become very excited about it, beating his head with his hands and sobbing. Without the statement in question he should have considered him insane. Mr. Harnett had declared his belief in a plot of which Dr. Adam was the central figure to shut him up and prevent him carrying out his mission. The injection with "tuberculin" by a quack was, in the opinion of the witness, probably an injection with coloured water. Tuberculin would not produce delirium, and he had regarded the supposed result of the injection as a delusion of the patient.

The plaintiff, recalled, said that his offer to preach at Borstal was inspired by the words, "I was in prison and ye came unto Me." He had believed that Dr. Penfold did not believe in God and had therefore asked Dr. Webster whether he did, wishing to be attended by him. He spoke of interviews with Dr. Cooper and of Dr. Cooper having told him that he was perfectly sane. He denied asking him to spell parallelogram. He gave an account of his interview with Dr. Cooper on Dec. 13th, 1912, and said he had told him the same story of his wife that he had told Sir J. Crichton-Browne. He denied kneeling on the floor, but when Dr. Cooper had walked to the fire-place he had knelt on what looked like a *prie-dieu*. He had not claimed supernatural power or that he was overshadowed by God; and Dr. Cooper's description of what occurred was "absolutely false."

The Attorney-General, for Dr. Bond, said that no doubt matters described as the plaintiff's delusions had been in some cases not delusions at all. It was practically impossible always to avoid this occurring. He did not contend that Mr. Harnett was insane at the end of his confinement, but asked the jury to consider whether the plaintiff was out of his mind on Dec. 14th, 1912. Did Dr. Bond honestly think him so? Was he reasonable in forming that opinion? Mr. Harnett was sent back to Malling Place in order that Dr. Adam might judge whether he was better or worse. If he was sane it was not Dr. Bond who was responsible for keeping him under restraint. The only trespass Dr. Bond might have committed was in detaining him at the Commissioners' offices.

Mr. Neilson, for Dr. Adam, submitted that after the reception order and in all the circumstances, Dr. Adam had acted honestly, reasonably, and properly, and done nothing that a properly minded man should not have done in the circumstances.

Mr. Justice Lush, summing up, said that the main point to consider was the plaintiff's mental condition when he went to the offices of the Commissioners in

Lunacy. He was then entitled to have his legal rights observed and the defendants must take the consequences if they had interfered with them without just cause. Dr. Bond had no more control over the plaintiff's personal rights then he (the judge) had. Dr. Adam, if he had disregarded the plaintiff's rights contrary to the law, must take the consequences. What could be more tragic than that if the plaintiff was sane (and he was admittedly a good business man) he should be taken off by keepers and confined with maniacs for nine long years in asylums? He referred to Lord Sandhurst's evidence in spite of which a doctor, a Commissioner in Lunacy, had reported the plaintiff as insane in 1921. His Lordship quoted from a version of the Mikado as to the spelling of parallelogram and said that he saw nothing remarkable in the plaintiff asking people to spell it. If the jury believed that what had been described as delusions were not delusions, and that the doctors had made a terrible mistake, and had kept the plaintiff in asylums when he was sane and able to express himself, it greatly helped the plaintiff's case. His condition during those years was a vital point, as it threw light on his condition in Dec. 14th, 1912. If he then had no delusions what was there to justify his detention?

His Lordship left to the jury the questions given above, and after their answers and their verdict as to damages had been returned heard argument mainly as to the apportionment of the damages.

Mr. Neilson also submitted that Dr. Adam was legally protected by Section 330 of the Lunacy Act, 1890, if he had acted with good faith and reasonable care. He referred to Shackleton *v.* Swift, 2 K.B., at page 316. His Lordship said that Dr. Adam should have seen the plaintiff before taking him back. Mr. Neilson referred further to Section 55 of the Act, which, he argued gave the visiting justices power to grant the order which they did in this case. A proviso enabled the manager to take the patient back. Mr. Neilson also referred to the answers to questions 9, 10, 11, arguing that answer 11 was inconsistent with answers 9 and 10. If Dr. Adam honestly believed that the plaintiff was unfit to be at large, he could not be held to have failed to exercise reasonable care in having him brought back to Malling Place. When he was brought back he was examined and retained there and the jury had not found that Dr. Adam had not been actuated by an honest belief. He asked for judgment on his behalf.

His Lordship in his judgment dealt at length with the various dates as to which the damages might be apportioned, and proceeded to the question of remoteness of damage, the point being whether the defendants by their acts and through the findings of the jury were liable to pay damages in respect of the whole period of the plaintiff's detention as insane—that is to say, from Dec. 14th, 1912, to Oct. 15th, 1921, when he escaped. It was contended that the damages were too remote if assessed for the whole period of detention, and that the chain of causation was broken by a *novus actus interveniens* when Dr. Adam found the plaintiff to be insane on his return to Malling Place, or when in February, 1913, he was removed to Croydon, or when in November, 1913, he was re-certified. In his Lordship's opinion there was no *novus actus interveniens*, and it was therefore quite open to the jury to treat the long detention as a direct consequence of the defendant's acts. He expressed the view that each fresh medical superintendent receiving a patient under his care would know his history as shown by previous reports, and would take these into account so that decisions by different doctors, commissioners, visitors, and medical superintendents were not fresh interventions breaking the chain of causation. The jury evidently thought the plaintiff was sane throughout the whole time. The alleged delusions were disposed of and the Attorney-General did not dispute that most of them were not delusions. As to Dr. Adam, he could and should have seen the plaintiff first instead of allowing him to be detained and fetched back. He was guilty of gross want of care in acting as he did. He had submitted the plaintiff to the shock of being brought back before he examined him. As to Dr. Bond, the jury had found that the plaintiff was not of unsound mind on Dec. 14th, 1912, and that Dr. Bond did not honestly believe that he was (Q. 5). They had found that Dr. Bond had formed a mistaken view (Q. 6). If Dr. Adam had ascertained the truth he might not have had to see the plaintiff at all or if he had gone he might have cleared the matter up. There was, in his Lordship's opinion, ample evidence to support the jury's findings. Under Section 330 of the Lunacy Act, 1890, he held that the onus of proof that an official exercised reasonable care was on the official. His Lordship gave judgment for £5000 against Dr. Bond personally, and for £20,000 jointly against him and Dr. Adam, with costs to follow the event. On the question of a stay of execution being raised, he ordered £5000 to be paid by Dr. Bond within a week to the plaintiff, and £20,000 to be paid into court or security given within three weeks, with an undertaking as to costs.

The case lasted altogether 18 days, commencing Feb. 6th and ending Feb. 29th.

Public Health Services.

THE LOCK-UP SURGERY IN INSURANCE PRACTICE.

IT is laid down in the terms of service (Clause 12) under the National Insurance Acts that the panel practitioner may not carry out his insurance practice elsewhere than at his place of residence, except under such conditions as appear to the Insurance Committee, or, on appeal, to the Ministry, to be compatible with efficient service. Under these terms a lock-up surgery may be conducted if the doctor has made suitable arrangements whereby he may be available to his panel patients at any time his attendance may be required. At a recent meeting of the London Insurance Committee the question of what constituted suitable arrangements was brought up in a report of the Medical Benefit Subcommittee, of which a section consisting of three representatives of the Insurance Committee, and an equal number from the Panel Committee, had been appointed to deal with this matter. The section considered all cases of insurance practitioners who do not reside at their respective surgeries, with a view to satisfying themselves as to the arrangements made. While under the terms of service the practitioner is required to notify his patients at his own expense of any special arrangements which he may make in carrying out his insurance duties, the regulations under the Act do not specify any details with regard to such arrangements, and the Insurance Committee have agreed with the Ministry that in urban areas arrangements such as the following might be reasonably considered adequate in the conduct of a lock-up surgery:—

1. That there be a resident caretaker in the surgery and that telephonic communication should be established between the surgery and the doctor's residence.
2. Where the doctor lives within the distance limited in accordance with the decision of the Insurance Committee of the area, the doctor's address should be posted up at the surgery where it shall be visible both by day and by night.
3. Where the doctor lives at a distance and only his deputy is available between certain hours, a written notice of the deputising arrangement should be given to each of the doctor's patients.

Every case is to be considered on its merits by the Insurance Committee after consultation with the Panel Committee, and the Insurance Committee may require that the patients are to be notified at the practitioner's expense of any special arrangements under which the practice is carried on.

A PROMPT SCHOOL MEDICAL REPORT.

THE first annual report of the school medical service to reach us for the year ending Dec. 31st, 1923, comes from Taunton. The chief feature of the year's work was the opening of a new clinic where minor ailments, defective vision, discharging ears, skin disease, and dental defects are treated. The clinic is to be a health centre where advice as well as treatment can be obtained. Parents are invited to bring any child they are anxious about to the centre for examination, between 9 and 10 A.M. No card is required for admission, and attendance is counted as school attendance. School inspection treatment, feeding, infant welfare work, in fact all public health activities are administered through one officer, Dr. John Allen. The school nurse is also school attendance officer—a successful combination in Taunton. The child is looked after by the health department from the cradle until he finds employment after school, except during the critical period between 3 and 5 years of age. And no doubt Dr. Allen will shortly find some means of bridging this ugly gap. The routine inspection of 1250 children revealed 229 requiring treatment, and in 88·6 per cent. of these cases it was obtained. The dental examination of 1804 children resulted in treatment for 1061 of the 1258 cases requiring it. Throughout the year, with the exception of the summer holidays, dinners were provided by the Education Committee. The average daily attendance was 52. A one-course meal, with, in addition, a daily allowance of 2 oz. of wholemeal bread, and twice a week uncooked fruit such as apples or oranges, was served. The cost was 1·7*d*. per child for food, and for administration 2·8*d*. All the administrative part of this work was dealt with by the medical department. Unfortunately, all the infant departments in Taunton were closed for two weeks in April on account of measles and whooping-cough. Altogether during the year there were 39 cases of measles and 62 of whooping-cough.

The Services.

ROYAL ARMY MEDICAL CORPS.

Col. J. Poe, late R.A.M.C., retires on ret. pay.

Capt. T. Young to be temp. Maj. whilst empld. as Dep. Asst. Dir. of Hygiene.

Capt. K. N. Purkis retires, receiving a gratuity.

TERRITORIAL ARMY.

Maj. (Prov.) A. S. Bruzaud, having attained the age limit, is retired and retains the rank of Capt.

Capt. J. B. Orr to be Bt. Maj.

Maj. D. V. Haig, having attained the age limit, is retired and retains the rank of Maj. with permission to wear the prescribed uniform.

Capts. F. S. Fletcher and J. L. Lawry, having attained the age limit, are retired and retain the rank of Capts.

Capt. (Prov.) J. G. B. Coleman, having attained the age limit, is retired and retains the rank of Lt.

Capt. C. D. Mathias to be Maj.

Capt. R. J. W. A. Cushing resigns his commn. and retains the rank of Capt.

Lt. J. S. Pegum resigns his commn. and retains the rank of Lt.

ROYAL AIR FORCE.

Capt. C. T. Hastings, Army Dental Corps, is granted a temp. commn. as a Flight Lt. on attachment for duty with the R.A.F.

DEATHS IN THE SERVICES.

Inspector-General Walter Reid, R.N. (retd.), who died at Okehampton on Feb. 27th in his eighty-fourth year, graduated M.D. at Edinburgh University in 1863, in which year he also obtained the L.R.C.S. Edin. He then joined the Royal Navy and saw service in the Ashanti War of 1874, when he was mentioned in despatches and received the medal. Among his contributions to medical literature was a case of Double Popliteal Aneurysm at Haslar, which appeared in THE LANCET in 1895. He retired with the rank of Inspector-General in 1898.

Correspondence.

"Audi alteram partem."

MEDICAL MEN, THE LAW, AND THE PUBLIC.

To the Editor of THE LANCET.

SIR,—Modifications in the relations between medical practitioners, the law, and the public, especially the section of it suffering from mental disorder, are evidently called for. On the one hand, there is a public, jealous that no one shall be deprived of his liberty on account of mental ill-health except for reasons which appeal even to the uninformed—i.e., that the patient should be the raving lunatic of popular imagination or the wild-eyed homicidal maniac lusting for blood—and but little realising that under a calm exterior there may lurk a state of mental disorder rendering the individual utterly incapable of looking after himself or of being anything but a source of misery, and possibly of danger, to those about him. On the other hand, there is our profession, regarding the individual as a patient to be cared for, treated, and kept from harming himself and others. We are loaded with the always disagreeable, frequently odious, and not infrequently dangerous responsibility of "certifying" the patient; with the uphill and wearing burden of endeavouring to ameliorate the mental state of our patients and of safely and comfortably housing them; and with the solution of the problem of returning patients to normal society only when we feel sure that they are fit for it, and if they are not quite well, of securing that they shall be, with advantages to themselves, properly and safely looked after.

We and the nurses who work with us are prevented by law from receiving such patients into homes and hospitals unless they are certified, and we may then only receive them if we are the officers of mental hospitals or of licensed houses or if we receive but one patient at a time. Certification is, in fact, forced by law upon us and upon our patients if they desire to be properly treated or if their relations on their behalf so desire. The law, in short, steps between us and our patients and often prevents the treatment we deem scientific and proper. The law does this because it wishes to safeguard liberty.

If, then, the public and its legal advisers are of opinion that the mentally disordered are in danger at the hands of unscrupulous doctors, let us ask to be allowed to hand over freely (and with delight) all the proceedings associated with certification, forcible detention and release, to the law and its police officers. We should then relinquish a burden which it appears we are judged too weak to carry and too dishonest to be entrusted with. Such would be a simple and to many a satisfactory solution. Let science stand down and let inexperience and ignorance prevail. In the result we could at least point out that medical treatment was not in our hands in those particulars but in those of the law and its officers, while complaints as to this part of treatment would have to be directed to other quarters.

For the community the result would be, I suggest, unsatisfactory. If under the present system liberty is on the rarest possible occasions infringed (and personally I have never known of a case of wrongful detention) so is it in every case where an alleged offender, subsequently proved innocent, is remanded to gaol, or when innocent persons are condemned to terms of imprisonment; but under an alternative system in which certification, detention, and release become matters of judicial concern, many a person of unsound mind will go untreated and uncared for, intolerable conditions will be created for many a family, and many and violent assaults will occur. But the community does not realise this or from what we save it. So be it; but surely our measure is overflowing. We have borne the burden sufficiently long. Let it pass to other shoulders, to those who are of opinion that they know better than we do.—I am, Sir, yours faithfully,

Harley-street, W., March 1st. E. D. MACNAMARA.

A STANDARD DIET FOR INSULIN TREATMENT.

To the Editor of THE LANCET.

SIR,—After a few months' use of insulin on orthodox lines it became apparent that if diabetics throughout the country were to obtain the full benefit of the new treatment it was necessary to work out a much more simple method of arranging the diet and general control of the treatment.

The scheme outlined below has been so successful that even in hospital practice I generally use it instead of the older and more elaborate methods of estimating basal diet, sugar tolerance, &c., and gradually building up a diet. The time required to ascertain the right diet and the necessary dose of insulin is much shorter, while the end-results are equally good.

The general principle of the method is to give from the outset a diet capable of producing the number of calories required by the average patient to carry on his ordinary life. Elsewhere I have shown that there are many fallacies in the usual method of working out the basal diet and that there is no constant relationship between this basal diet and the adequate diet, but that the number of calories required by the average patient for an adequate diet is fairly constant. This diet is given, and if the patient cannot metabolise it without help he is given sufficient insulin to enable him to do so.

From the treatment of about 80 cases of diabetes it appeared that the average number of calories required daily was about 2300, and this was the number fixed on. The next question was how this number of calories should be made up. The amount of protein was fixed first. This must not be too low or body repair and growth cannot be maintained; it should not be too high or an unnecessary strain is thrown on the kidneys and the amount of potential carbohydrate may be excessive. Of the two faults it is obviously safer to give too much than too little. Disregarding the theoretical number of grammes per kilo of body-weight, about which the various authorities differ widely, I took Hutchison's broad estimate of the minimum requirements of the average man—viz., 80 g. of protein daily. This amount of protein will produce 320 calories. The remaining calories are made up from carbohydrate and fat and a satisfactory proportion of each is fixed. There has been much written about ketogenic and anti-ketogenic diets, but as a matter of fact some patients tolerate a much larger proportion of fat than others. Woodyatt's rule, however, is a useful one and in most cases errs on the safe side. The rule is that the fat should not exceed twice the carbohydrate plus half the protein. Taking the protein at 80 g., the carbohydrate would be 70 g., and the fat 185 g. if we take the nearest round figures necessary to maintain the right carbohydrate fat ratio and to produce in all about 2300 calories. These were the quantities taken in fixing the adequate diet which, for convenience, I called the "standard diet."

While it is easy for those of us who are constantly at it to work out different diets containing these proportions of carbohydrate, protein, and fat, the busy practitioner will find it an advantage to have one worked out for him, and the following example shows how it may be done with ordinary food-stuffs which suit the average taste. Of course, by studying the constituents of all the different articles of food the diet may be varied indefinitely so long as approximately the right amount of each constituent is retained. Anyone who has not the time or inclination to do so may confidently order the diet given below. A mild case, or one of average severity, where there is little acidosis or de-nutrition, need not stay in bed at all, and if his work is not very arduous, may carry on his usual life. Accurate diagnosis is *essential*. If clinical signs and symptoms are not conclusive of true diabetes a blood-sugar estimation must be done before commencing treatment.

"*Standard Diet.*"

Food.	Carbo-hydrate.	Protein.	Fat.
Three eggs	—	18	18
12 oz. 5 per cent. (green) vegetables	12	3	—
3 oz. butter	—	—	72
2½ oz. beef or mutton (lean)	—	20	12
2 oz. ham	—	12	16
2 oz. bacon	—	6	30
¼ oz. milk	6	4	4
1 oz. cream (thin)	1	1	6
½ oz. olive oil	—	—	15
2 oz. brown bread	26	3	1
¼ oz. porridge	18	4	2
1 oz. potato	6	1	—
1 oz. cheese (cheddar)	1	8	9
	70	80	185

In the case of meat, potato, &c., the weight given is that of the cooked article. If porridge is not liked an extra ounce of bread may be allowed, or half an ounce extra bread may be given if the potato be omitted. Again, instead of the ham, a patient may be allowed two ounces of fish and half an ounce extra butter, and so on. Weak tea, weak coffee, or beef-tea may be taken freely. The distribution of the meals may be left to the patient, but when insulin is given the meal following the dose should contain a fair proportion of the carbohydrate allowance. In most cases it is better to get the patient on to this diet gradually, and the directions I usually give are as follows:—

1st day	Diet as above but take	4 oz. bread,	1 oz. butter.
2nd day		3½ "	1½ "
3rd day		3 "	2 "
4th day		2½ "	2½ "

5th day, standard diet with 2 oz. bread and 3 oz. butter.

During this stage it is *essential* to test the urine each day for acetone or diacetic acid, and desirable to test it for sugar at the same time. The simplest plan is to instruct the patient how to test his own urine for sugar with Fehling's or Benedict's solution, and for diacetic acid by adding a little weak ferri perchloride solution to an inch of urine in a test-tube. He is instructed to report at once if any red colour is given with the latter test. If diacetic acid appears at all, or if acetone is present in any quantity, the amount of bread must be increased and the amount of butter diminished until the acidosis disappears. Another attempt may then be made by adjusting the amounts more gradually, or insulin started without further delay. If, however, no diacetic acid appears when the standard diet is reached the sugar may or may not have disappeared. If it has apparently gone specimens of urine at different times of day, especially an hour to an hour and a half after the meal containing the most carbohydrate, should be examined to make sure that the patient is really sugar-free. If so, go on with the diet, getting the patient to test the urine every day at first and afterwards once or twice a week. If weight, energy, and sense of well-being are normal continue indefinitely; if not, increase the diet first by adding more butter, cream or oil, keeping a sharp look out for acidosis. After the maximum amount of fat which can be tolerated is reached any further increase must take the form of bread or other carbohydrate. If sugar now reappears treat the case as described below where sugar has persisted from the first.

If there is still sugar in the urine after a week on the standard diet, or sooner if the amount of sugar is high, begin insulin treatment. Keep the diet the same, but give gradually increasing doses of insulin until the glycosuria is controlled. How is this done? Two specimens of urine are examined daily, one taken an hour to an hour and a half after supper, and the other before breakfast. Increase the insulin until there is just the faintest trace of sugar in one or other of these specimens. Whether the dose is pushed beyond this point depends, in the absence of blood-sugar estimation, on the intelligence of the patient and the amount of control available. If there is little opportunity for supervision, or the patient is not very intelligent, it is wiser to be content with this dose. On the other hand, an intelligent patient can usually increase the

dose of insulin unit by unit so as to keep the urine entirely sugar-free and make certain that his blood-sugar is about the normal level. A feeling of slight malaise warns him when he is having rather much, and he continues with a dose slightly less than this amount. During this time the diet is, of course, constant.

When should the insulin be given and how should the dose be increased? Start with 5 units before breakfast and increase to 10, 15, or 20 units at the same time. If more than 20 units are needed give two doses a day, one before breakfast and the other before tea, giving the larger dose before breakfast. Do not increase by more than 5 units at a time. At first the increase may be made every day, but when the sugar is getting small in amount the intervals should be longer and the increase should be by 1 or 2 units instead of 5. Never give insulin near bedtime. If this routine is carefully followed the danger of serious hypoglycæmia is negligible, although it is well for the patient to have a little glucose always available. The patient is taught to give himself the insulin as well as to test his own urine. He keeps a note of the dosage and the urinary findings and reports to the doctor from time to time.

As long as the patient feels well and his urine is normal he goes on with the standard diet and the requisite amount of insulin. If the diet is inadequate it is increased on the lines previously described—viz., first by increasing the fat so far as this can be done without the appearance of acidosis, and secondly by increasing the carbohydrate. If the latter is necessary there will be a recurrence of glycosuria which must be met by a further increase of insulin. On the other hand, if the diet proves to be slightly in excess of requirements, a rare occurrence, both the diet and the dose of insulin are reduced. In the great majority of cases, however, the standard diet is about right, and, with or without the help of insulin, the patient will maintain a normal weight and have sufficient energy to carry on his usual life in health and comfort. More severe cases where there is marked acidosis, denutrition, threatened coma or gangrene, should be kept strictly in bed. They should have a diet comparatively rich in carbohydrate and poor in fat, while insulin is administered from the outset. Once the acidosis is overcome the diet is adjusted until the standard diet is reached, and the amount of insulin necessary to metabolise this diet is ascertained as before.

By following this simple scheme of treatment most sufferers from diabetes can get adequate treatment at the hands of their own doctors, and complications of the disease, such as coma and gangrene, will in great measure be abolished.

I am, Sir, yours faithfully,

Swansea, Feb. 25th, 1924. A. CLARKE BEGG.

HUMANITY OF METHODS OF SLAUGHTER.

To the Editor of THE LANCET.

SIR,—Apropos of Dr. Leonard Hill's article in your issue of Dec. 22nd, 1923, and the letter from Dr. Duncan Forbes advocating the abolition of the pole-axe for the slaughter of oxen, it may be of interest to record the experience of Mr. C. E. Hagley, superintendent of the Bloemfontein municipal abattoir. There the humane-killer has been employed during the past 11 years for the slaughtering of 51,723 bovines and 11,813 pigs. Throughout this period there has been no accident, the nearest approach to one being with the first gun issued, which had the striker unprotected. A restless ox struck the striker with its horns, but the bullet penetrated the skull and dropped the animal. The humane-killer is handled only by the superintendent and his assistants; native slaughter-men are not allowed to use it. During the period it has been in use there have been no complaints concerning insufficient bleeding or the keeping quality of the meat of animals killed by this method.

I am, Sir, yours faithfully,

W. A. BERRY,

Feb. 14th, 1924. Medical Officer of Health, Bloemfontein.

IN THE MATTER OF "DICHOTOMY."

To the Editor of THE LANCET.

SIR,—In compliance with a widely felt desire, a meeting of the consultants and specialists of this city was held at the Birmingham Medical Institute on Monday, Feb. 25th, for the consideration of the subject of "dichotomy" or fee-sharing. The meeting was very largely attended and letters were received from a few who were absent. After full discussion, including reference to the numerous cases in which patients ask what will be the total cost of treatment in a nursing-home or private hospital, the following resolutions were passed unanimously:—

1. It is improper for a Consultant to transfer any portion of his consultation- or operation-fee to the Practitioner who has called him in. The Consultant who offers or agrees to such payment, however innocently, is open to the suspicion of paying a "commission" for his own advantage. The Practitioner who accepts or asks for it cannot maintain the position of a trusted and unbiased adviser as to the need for a consultation and the selection of a Consultant.

2. No Consultant or Specialist shall pay to the General Practitioner who is associated with him in a case any part of an operation-, consultation-, or so-called "inclusive" fee, unless he informs the patient or his representatives of the services for which the payment is made and the amount of such payment.

It was further resolved that a report of the meeting should be sent to every consultant and specialist in the Birmingham district for his or her signature as evidence of agreement, and to all members of the medical profession in the district for their information.

PRIESTLEY SMITH, Chairman of the Meeting.
LEONARD G. PARSONS, A. W. NUTHALL, Secretaries.

Birmingham, Feb. 28th, 1924.

LEPROSY: A SELF-HEALING DISEASE.

To the Editor of THE LANCET.

SIR,—In the report of the meeting at the Mansion House in support of the British Empire Relief Association in your issue of Feb. 9th, Sir Leonard Rogers is stated to have "briefly outlined the researches which enabled him to establish the important principle that by the injection of soluble products of the active portions of the old Indian remedy for leprosy, chaulmoogra oil, the bacillus of the disease could be destroyed within the body, with clearing up of all symptoms, as well as of the infectivity of the disease, and that similar preparations derived from cod-liver and other oils were also effective in leprosy." And in a leading article summarising the views of Dr. Ernest Muir it is stated that during the first two stages of the disease "the chief object of treatment is to restore the lowered tissue resistance."

In papers which you have been good enough to publish in THE LANCET at various times in the last ten years I have endeavoured especially to show that an increase of lipase in the blood and tissues is an important factor in natural and therapeutic immunisation and induced resistance. I hope this aspect may not be lost sight of in the present campaign. With regard to leprosy, in the *Journal of Tropical Medicine and Hygiene*, 1921, xxiv., 161 (referring to the treatment by sodium chaulmoograte and sodium morrhuate in leprosy and tuberculosis introduced by Sir Leonard Rogers), I pointed out that these salts increased the action of lipase in vitro in the same way as sodium oleate; that in view of the ascertained action of sodium oleate in vivo, "it would seem reasonable to infer a direct stimulating action primarily of tissue lipolysis in explanation of the therapeutic effect of sodium morrhuate, and at any rate, part explanation of the effect of sodium gynocardate (chaulmoograte)." I went on to say, "the idea or principle underlying treatment is the production of the lipolytic ferment in the tissues which in tuberculosis acts on

the fats and lipoids of the tubercle bacillus and is injurious to it; and presumable also in leprosy on the lepra bacillus." The main outcome of my research work has been to show that natural and increased production of lipase or fat-splitting ferment in the blood and tissues is an important factor in the protective processes or induced resistance of the body. I am, Sir, yours faithfully,

J. A. SHAW-MACKENZIE, M.D. Lond.

King's College, London, Feb. 29th, 1924.

TREATMENT OF UTERINE FIBROIDS.

To the Editor of THE LANCET.

SIR,—The discussion held on Feb. 25th at the Medical Society, and reported last week in your columns, gives radiologists an opportunity of revising their views. Briefly the position is as follows. Gynæcologists either (1) rely largely on X rays in selected cases; (2) fear X rays as uncertain in their cure; or (3) dread possible injury to healthy tissues.

My own view is: (1) That the diagnosis of fibroid uterus should be made by a skilled gynæcologist, if necessary under a general anæsthetic. (2) Cases should be carefully selected; women nearing the menopause with small fibroids, causing hæmorrhage, are specially suitable. (3) Ovarian cysts and tumours or suppurative diseases of the ovaries, tubes, or uterus are unsuitable for X ray treatment. In selected cases the results are all that can be desired. As to technique, those who have adopted the Erlangen method of deep X ray therapy are inclined to apply it to fibroids. An inoperable cancer may justify a desperate remedy, which may inflict considerable damage on healthy structures, but it is unnecessary to subject patients with fibroids to the discomfort and malaise which almost invariably follows the Erlangen treatment.

Radiologists are *not* justified in damaging healthy tissue while curing fibroids, nor need they. With Coolidge tubes and modern apparatus, dosage and penetration can be measured with great accuracy, and the soft rays which injure the skin can be filtered out. The exact dose can be repeated at will, and no damage need accrue from X ray treatment.

I am, Sir, yours faithfully,

Upper Wimpole-street, March 3rd. ALFRED C. JORDAN.

AUTO-HÆMO-THERAPY.

To the Editor of THE LANCET.

SIR,—Dr. S. G. Billington's interesting article in your last issue on Auto-hæmo-therapy, describing the results obtained by the use, in certain infections, of a "hæmo-vaccine" composed of coccoid bodies derived from the blood, brings up a question which I believe will prove to be of considerable importance. In a paper intended for publication I have noted the formation of small spheres and granules produced by the exposure of washed red cells to the rays of the tropical sun, even for only a few minutes. These granules, which I take it are of the same nature as the coccoid bodies described by Dr. Billington, are evidently the products of the disintegration of red cells. I have endeavoured to show that such disintegration products, whether produced by the action of the sun, by heat to 56° C., by grinding in a mortar, or by bacterial action are toxic, and that some of the phenomena of bacterial infection may be attributed to this toxin rather than directly to a bacterial toxin. Further, that the injection of destroyed red cells has a therapeutic value, presumably by setting up an immunity to the toxin which is the cause, wholly or in part, of the symptoms of the disease. Though we have approached the subject from different angles and employ an entirely different technique, I believe that Dr. Billington and myself are dealing with the same phenomenon—namely, the toxic nature of red cells just sufficiently destroyed to allow of their stroma being diffused into the circulation.

I am, Sir, yours faithfully,

Leicester, March 2nd, 1924. T. C. CLARE.

Obituary.

ROBERT GUTHRIE POOLE LANSDOWN, M.D., B.S. DURH.

THE sudden death of Mr. R. G. P. Lansdown consulting surgeon to the Bristol General Hospital occurred on Feb. 17th in a syncopal attack, at the ag of 60. The news of his death was received with consternation by all who knew him, for he had been i full work up to the morning of his death.

Mr. Lansdown was born in September, 1863, i Bristol. His father, Francis Poole Lansdown, wa surgeon to the Bristol General Hospital from 1861 t 1893, and his grandfather, Joseph Goodale Lansdown held the same post from 1832 to 1861, being a membe of the original staff of the hospital. Robert Lansdow was educated at Clifton College and Epsom College passed his preliminary science examination fro University College, Bristol, and went on to complet his professional training at Guy's. In 1889 he passe his M.B., B.S. examination at Durham, gained hi Conjoint diploma in 1890, and took his M.D. Durh in 1891. After serving as clinical assistant, assistan house surgeon, house surgeon, and resident obstetri officer at Guy's, he joined his father in practice a Clifton in 1891. Almost at once he became associate with the Bristol General Hospital, an associatio which continued till his death and was the dominan factor in his professional life. His first appointmen to the hospital was that of anæsthetist, which he hel till 1893, when he was appointed assistant surgeon becoming a full surgeon three years later. In 1918 h became dean of the honorary staff, retiring fro active service in September, 1923, under the age rul of the hospital. On his retirement he was electe a consulting surgeon to the hospital, and proceede to prove that his office was more than a mere titl by attending regularly at the weekly surgical consulta tions with his colleagues. To these years of hospita work he gave the most devoted service. He wa a true friend to everyone connected with the plac and gave himself to upholding and raising the standar of its work in all phases of its activity. In 1902 h dropped his general practice and limited himself t consulting surgery; but his experience of genera practice stood him in good stead, and was reflected i his relations with the practitioners of the distric as well as in the very practical character of his surgica teaching. In addition to his work as dean of th hospital staff, he did good service as lecturer o practical surgery for a number of years at the Univer sity College (later the University) of Bristol, an held many other offices in the University. Hi interest was always in clinical work, and he lost n opportunity of imparting the fruits of a wide experi ence to his students as well as his colleagues. H was extremely methodical and neat in his way and this was particularly to be observed in his surgica technique. No matter how great the demands on hi time he was always able to give his attentive considera tion to any question put before him. During muc of his surgical career he gave a great deal of though to the provision of private hospital accommodation At the time of his death he was chairman of th committee of the Chesterfield Place Nursing Hom and was largely responsible for recent development destined to enlarge it and convert it into a first-clas private hospital. Soon after settling in Bristol h became Surgeon-Captain to the Gloucestershire Roya Artillery Volunteers, and retained this appointment fo many years. On the outbreak of war in 1914 he wa mobilised with the Second Southern General Hospita as a Major in the Territorial Force, and until it demobilisation in 1919 continued to serve as surgeon t the Royal Infirmary section of that unit. He occupie the presidential chair of the Bath and Bristol branc of the British Medical Association, and also of th Bristol Medico-Chirurgical Society. For 24 years h was honorary surgeon to the Clergy Daughters

School. As a governor of the Queen Victoria Jubilee Convalescent Home he concerned himself much with the provision of time and place for recovery after operations and serious illness. He was the author of many papers on surgical subjects which appeared in various professional journals.

Lansdown was a diligent worker, but he was also a very good holiday-maker. Wherever he went he found occasions for his two great hobbies, motoring and photography. Less than 48 hours before his death he gave a delightful address to the Bristol Medical Club on "Rambles," illustrated by a number of beautiful lantern-slides taken on his holidays. There were many other activities that went to make a very full life. One trait in particular, his aptitude for acting, gave him much pleasure and made him a mainstay of the Bristol Medical Dramatic Society. In his time he was a good swimmer and received the bronze medal of the Royal Humane Society for saving a child from drowning in a rough sea at the imminent risk to his own life in the summer of 1883 near Torquay.

A colleague writes of him: "Lansdown was a most loyal friend and was always willing to listen to the troubles of other people and give help and advice. He was not easily dismayed by adverse circumstances and was often responsible for rallying a forlorn hope and leading it to victory. His cool and steady judgment was a great asset to the institutions with which he was connected, and his death is a grievous blow to the work of his profession in Bristol."

A sense of this loss received striking expression in the very large attendance of doctors at his funeral service on Feb. 20th at St. Paul's, Clifton, where he was a sidesman and had attended service only a few hours before his death. Mr. Lansdown married, in 1893, Miss Alice Anna Griffiths, of Cardigan, who survives him, with a son, who is a medical man, and a daughter.

JOHNSON SYMINGTON, M.D. EDIN., F.R.C.S. ENG. AND EDIN.

Dr. Johnson Symington, emeritus professor of anatomy at Queen's University, Belfast, died on Feb. 24th in Edinburgh, aged 72. Prof. Symington was born in 1851 and was educated at Taunton and at Edinburgh University, where he graduated in medicine in 1877. Later he was appointed lecturer in anatomy at the Minto-street extra-mural school in Edinburgh, and his success as a teacher there gained for him, after some years, the chair of anatomy in Queen's College, now Queen's University, Belfast. Prof. Symington held many various administrative and educational offices. He was examiner in the Royal University of Ireland, of which he was an ex-Fellow, and in 1903 he was appointed President of the Section of Anthropology at the British Association Meeting in Southport. For three years, from 1904 to 1906, he was President of the Anatomical Society of Great Britain and Ireland. The honorary degree of LL.D. was conferred upon him by Queen's University, Belfast, and in 1903 he became a Fellow of the Royal Society.

We have received the following appreciation of Prof. Symington from his colleague, Prof. T. H. Milroy, M.D.:—

"Practically from the beginning of his undergraduate career until the close of an active professional life, Johnson Symington devoted himself to the subject of anatomy, and the keen zest, natural to the young worker, never showed any sign of abatement with the passage of the years. From the very outset he recognised that teaching and investigation must go hand in hand, and, although both at Minto House, Edinburgh, and in Belfast his fame as a teacher might in some respects have satisfied him, he never allowed his love of teaching to encroach upon his activities as an investigator. At all times the outlet for his energetic personality was research, and thus British anatomy owes him a deep debt of gratitude for valuable contributions in many departments of topographical anatomy. While lecturer in anatomy in Minto House, Edinburgh, he published a number of papers in the *Journal of Anatomy*, dealing with applied anatomy, the structure of the central nervous system, and splanchnology. During his period of tenure of the Belfast chair, he published his most important work. From 1903 onwards his interests were mainly centred upon cranio-cerebral topography. In 1903 he described a method devised in order to demonstrate the relations of the deeper parts of the brain to the surface, and from this period onwards until the publication of the work in 'Quain's Anatomy' and elsewhere, he carried out an elaborate series of investigations with a wealth of material which must have aroused the envy of many less favoured teachers. Under the joint editorship of Sir Edward Sharpey Schafer and Prof. Symington, Part 1 of Vol. III. of 'Quain's Anatomy' dealing with the anatomy of the central nervous system appeared in 1908, and in this volume the results of many years' fruitful labour were incorporated, the macroscopic sections being left entirely in Symington's hands. Part 2 of this volume, dealing with the peripheral nervous system and sense organs, was published under the same editorship in the following year. In 1914 the volume on splanchnology appeared under the editorship of Symington, assisted by Dr. P. T. Crymble, and for this volume, as in the case of the preceding ones, an immense amount of work was carried out in his department. The work of so many years' strenuous research received due recognition by his fellow anatomists.

Although so actively engaged in his own department, he did not allow this work to monopolise his attention, and so we find him as the years went on playing a more and more important part in general university administration. During 24 years of active service in Ireland he devoted himself wholeheartedly to the interests of the old Queen's College and later the Queen's University of Belfast. As registrar, senator, and university commissioner he served his college in a way which will never be forgotten. The University of Belfast has good cause for revering the memory of one who never spared himself in maintaining and advancing her interests. His old pupils in Belfast and Edinburgh will be pleased to learn how highly their old chief appreciated their generosity in raising funds to endow a prize bearing his name to be awarded for research by junior anatomists on anatomical subjects. He was delighted to learn that the Anatomical Society had made their first award of this prize about a year ago. May his fine example of devoted service inspire young anatomists to follow in his footsteps."

Prof. Symington was a widower, and to his daughter we offer sincere sympathy in her bereavement.

HENRY WALTER VERDON, F.R.C.S. ENG.

Dr. Verdon, who died on Feb. 25th at Streatham Hill in the seventy-fourth year of life, was a man of all-round culture and a barrister-at-law of the Middle Temple. He qualified M.R.C.S. from St. Thomas's Hospital in 1873, continuing his studies at Paris and Brussels, and taking the Fellowship in 1876. After holding resident appointments, both at St. Thomas's and Westminster Hospitals, he settled down in general practice in the south of London, diseases of the heart gradually becoming his chief interest, and finally his specialty. A series of books and pamphlets on angina pectoris came from his pen, the last of which, appearing in 1920, laid stress on the hyper-irritability of the central nervous system as the basis of the anginous habit. In this work he was able to draw upon a large storehouse of facts and observations coming under his own experience. Dr. Verdon was a fine example of the utilisation of a general practice for intensive study of a special problem.

WILLIAM ARTHUR BOND, M.D. CAMB., M.R.C.P. LOND.

WE regret to record the death of Dr. W. A. Bond, who only retired in 1921 from the chief health officership of Holborn. His death occurred at Torquay on Feb. 20th as the result of pneumonia following on influenza. Dr. Bond was educated at King Edward VI. School, Norwich, and St. John's College, Cambridge, where he was a scholar and graduated as fourteenth wrangler. He went on to St. Thomas's Hospital, holding there the position of house physician, and later house appointments at Queen Charlotte's and the South-Western Fever Hospitals. For a while he studied in Paris, after which he took the M.R.C.P. Lond. His earliest public health work was done as medical officer to the St. Olave and Holborn

District Boards of Works, when he gained experience of the hygienic problems of meat storage and transport, which then needed much attention. When Holborn amalgamated with St. Giles, Dr. Bond became full-time medical officer of health for the combined Metropolitan Borough of Holborn, an appointment which engrossed all the busiest years of an active life. Gradually his recommendations resulted in a thorough overhauling of meat inspection, and in a series of prosecutions which initiated reform. Outside his official life he was active in his profession, being hon. secretary to the Royal Institute of Public Health and one of the earliest supporters of the Society of Medical Officers of Health, which for several years actually met at his office. His work was careful and systematic, and his writings, both official and quasi-popular, were lucid and finished. Although he did nothing to bring himself prominently into the public eye, the public health service will remember Dr. Bond with honour and gratitude.

EFFINGHAM CARROLL MACDOWEL, M.D. DUB., F.R.C.P. IREL.

Dr. E. C. MacDowel, surgeon to the Sligo County Infirmary, died on Feb. 23rd, after a protracted illness, at the age of 73. Born in 1851, he was the eldest son of the late Dr. Benjamin MacDowel, professor of anatomy and chirurgery in Trinity College, Dublin. He was educated at Trinity College, where he graduated Bachelor of Arts, had a distinguished student career both in arts and in medicine, and later went to Oxford University as Radcliffe Medical Scholar. Having obtained his A.B. he took the M.D. Dub. in 1875. While still a young man he was elected surgeon to the Sligo County Infirmary and he continued to perform the duties of that post for some 46 years until a few months ago. He was also visiting physician to the Sligo and Leitrim District Lunatic Asylum. In 1883 he became a Fellow of the Royal College of Physicians of Ireland, a qualification which was exceptional among country practitioners in Ireland. In the year 1907–08 he was president of the Irish Medical Association, which in that year held its annual meeting in Sligo. Dr. MacDowel was one of the leading practitioners in the west of Ireland and for many years he enjoyed a large consulting practice. He was a man of much culture, a sound diagnostician, possessed of considerable operative skill, and he took much pains to keep abreast of the advances in medical and surgical knowledge. His health had suffered since he lost his eldest son in the war. His next surviving son, Dr. F. L. H. MacDowel, is a surgeon in the Navy.

THE LATE DR. T. DOBSON.—The death occurred recently of Thomas Dobson, M.D. St. And., of Windermere, in his eighty-third year. Born in 1840 he studied at Charing Cross Hospital, and in 1862 he qualified M.R.C.S. and obtained the M.D. St. Andrews. In the same year he went to Windermere as assistant in a practice which he took over a few years later. As a practitioner he enjoyed success and respect in the district, and to his professional qualities was added a charm of manner which endeared him to his patients. He retired in 1888, and since then had continued in many useful public activities.

WORTHING HOSPITAL.—An important extension of this hospital was determined on at the annual meeting of the governors held on Feb. 29th, the idea being to increase the number of beds from 46 to 100. It was not thought possible to proceed with the scheme as a whole at once, but the present men's and women's wards will be enlarged first, with the object of securing the recognition of the hospital as a training centre for nurses. In 1920 the excess of expenditure over income was £1035. In 1921 this figure dropped to £453, and in 1922 to £135, but in 1923, notwithstanding the fact that the total expenditure was £734 in excess of the expenditure in the previous year, there was a balance in hand of £662. This was due largely to the result of the household box scheme, the amount received from this source during the year amounting to £1538, and since its inauguration to the sum of £1820.

Medical News.

UNIVERSITY OF OXFORD. — *Rolleston Memorial Prize, 1924.*—This prize, which is now of the value of about £100, is awarded every two years, under the condition stated below, for original research in any subject comprised in the following list: Animal and Vegetable Morphology, Physiology and Pathology; and Anthropology. A candidate will be eligible (1) who has not either passed the examinations for the B.A. degree or the B.M. degree at Oxford, or for the B.A. degree or the M.B. degree at Cambridge, or been admitted as a candidate for the degree of B.Sc. at Oxford or as an advanced student for the degree of B.A. at Cambridge; (2) who has exceeded a period of six years from attaining one or other of these qualifications, or from his attaining the first of such qualifications if he has attained more than one; (3) who has exceeded ten years from his matriculation. The next award will be made in Trinity Term, 1924. Candidates wishing to compete must forward their memoirs to the Registrar of the University of Oxford before March 31st, 1924. The memoirs may be printed, typewritten, or in manuscript; should be inscribed "Rolleston Memorial Essay"; and should bear the name and address of the author. Memoirs already published are admitted to the competition. No account will be taken of any research which has not been prosecuted by the candidate subsequent to his matriculation.

Christopher Welch Scholarship in Biology, 1924.—An examination for this scholarship will be held at the University Museum in July, 1924. Candidates must be undergraduate members of the University who have not exceeded the twelfth term from their matriculation. They may offer any one of the subjects Botany, Animal Physiology, Zoology, and they must give notice of the subject selected by them to the Registrar of the University not later than March 1st, 1924. They must further enter their names in person or by letter at the University Registry not later than Tuesday, April 1st, and must at the same time produce or send to the Registrar of the University evidence of their capacity for original observation and research. A candidate may also submit to the examiners any original work previously done by him.

UNIVERSITY OF LONDON. — A meeting of the Senate was held on Feb. 27th, the Vice-Chancellor, Mr. H. A. Waring, being in the chair. Mr. Richard Lake has been appointed as the first holder of the Geoffrey E. Duvet Lectureship in Otology, as from Jan. 1st, 1924. Mr. F. J. Steward was appointed to represent the University on the Council of the Fellowship of Medicine.—In connexion with a scheme which the Senate have under consideration, the Vice-Chancellor announced that the Chancellor (the Earl of Rosebery) had handed to the Principal Officer a cheque for £5000 in contribution towards the sum needed for the acquisition of an athletic ground for the use of the students of the University. A resolution was adopted conveying the warmest thanks of the Senate to the Chancellor for his gift.

THE annual conference of the British Hospital Association is to be held in London on Thursday and Friday, June 19th and 20th.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The second half of the intensive course at the Royal Northern Hospital will begin on Monday, March 10th, and continue throughout the week. Apart from the demonstrations and lectures by members of the Royal Northern staff, the course will include a demonstration on Wednesday morning, March 12th, at the North-Eastern Fever Hospital, and on Thursday afternoon, March 13th, at the Central London Ophthalmic Hospital. A special course in Gynæcology at the Chelsea Hospital for Women began on Monday last, and will continue till the end of the month. Entry may be made at any time for the remainder of the course, which consists of clinical demonstrations in the wards and out-patient department, followed by lectures on operations in the theatre. At the Royal Free Hospital on Wednesdays, at 5.30 P.M., Dr. C. B. Heald is giving a series of lecture-demonstrations on recent advances in medicine electrical treatment. Beginning on March 8th, at 11 A.M. and on successive Tuesdays and Saturdays, Dr. Porter Phillips and Dr. Thomas Beaton are giving a series of clinical lectures on the Diagnosis and Symptomatology of Mental Diseases, the Psychoneuroses, and the Medico-legal Aspect of Insanity. At the Royal Waterloo Hospital for Children and Women there will be given a three weeks' course on diseases of children from March 17th to April 5th. The course will occupy each afternoon with lectures, demonstrations, ward work, and out-patient clinique. Full particulars regarding any of the above courses, with copies of each syllabus, will be forwarded on application to the Secretary to the Fellowship of Medicine, 1, Wimpole-street, W. 1.

FOOD EDUCATION SOCIETY.—Dr. Harry Campbell and Sir Harry Baldwin have been respectively elected chairman and vice-chairman of this society.

ENCEPHALITIS LETHARGICA IN MANCHESTER.—In the week ending March 1st 13 cases were reported, and in the previous week 16 cases with 2 deaths. The first case in the present outbreak was notified on Jan. 2nd; on Feb. 2nd, 3 cases; on Feb. 9th, 9; on Feb. 16th, 13; and on Feb. 23rd, 16 cases were notified. This year the deaths have numbered 5 out of 42 cases.

ACADÉMIE DES SCIENCES ET LETTRES DE MONTPELLIER.—Two Alphonse Jaumes prizes will be awarded in 1925, one for an essay on a subject of general therapeutic interest, and one for an essay on a medico-legal theme. Each prize will be of the value of 2000 francs. Essays, written or printed, should be in French, and should be deposited before Dec. 31st at the Secretariat of the Académie. Further particulars can be obtained from Mr. F. Carrieu, 5bis, rue de la Merci, Montpellier.

FOOT-AND-MOUTH DISEASE COMMITTEE.—A committee has been appointed by the Ministry of Agriculture "to initiate, direct, and conduct investigations into foot-and-mouth disease, either in this country or elsewhere, with the view of discovering means whereby the invasion of the disease may be rendered less harmful to agriculture." The personnel of the Committee is as follows: Sir Charles Sherrington, P.R.S. (chairman), Dr. J. A. Arkwright, Prof. W. Bulloch, F.R.S., Prof. J. B. Buxton, Captain S. R. Douglas, F.R.S., Mr. S. H. Caiger, Sir John McFadyean, Prof. C. J. Martin, F.R.S., Prof. Robert Muir, F.R.S., Sir Stewart Stockman, Mr. H. G. Richardson, and Mr. W. G. Wragg (secretaries).

CHADWICK PUBLIC LECTURES.—A lecture, illustrated by lantern slides, on the Small-pox and Vaccination Question To-Day, will be given by Dr. C. Killick Millard in the Council Chamber, Old County Hall, Spring Gardens, Charing Cross, London, W.C., on March 10th, at 5.15 P.M. Sir Arthur Newsholme will preside.—A lecture, illustrated by diagrams, on the Sanitary Inspector in the Machinery of the Public Health Service will be given by Mr. John T. Quinton, in the same place, on March 28th, at 8 P.M., Sir William Collins presiding. Admission is free to both lectures.

INSURANCE FUNDS AND VOLUNTARY HOSPITALS.—At the annual meeting of the Manchester Children's Hospital the chairman, Lord Colwyn, called attention to the fact that one-half of the patients who came to these hospitals were insured under the Insurance Acts. Actuarial examination showed that the funds accumulated under these Acts show a surplus of £17,000,000, but the hospitals got nothing from the funds. It costs, he said, £5,000,000 a year to deal in the hospitals with these insured persons, and that sum voluntary subscribers from among the generous public have to pay, and he expressed the view that hospitals have a fair and justifiable claim on this fund. But for the special grants of £5000 from the proceeds of the Lord Mayor's Fund, and £1500 from the Voluntary Hospitals Commission, and for the fact that the subscriptions were £900 more than last year, there would have been a heavy deficit on the year's working.

LARGE SCALE PRODUCTION OF INSULIN BY THE "ACETONE-PICRATE PROCESS."—The Finance Committee of the Middlesex Hospital Medical School, at their meeting on Feb. 26th, report that so satisfactory has the new process recorded in THE LANCET (Feb. 16th, 1924, p. 330) by Dr. E. C. Dodds and Dr. F. Dickens turned out that large amounts of insulin can be prepared at a much reduced cost. Their process has been found to be eminently suited to the production of insulin on a large scale. It is to be understood that the insulin prepared in the Biochemical Department is only for experimental purposes and for the supply to cases of diabetes under treatment in the hospital, but, on going into the matter of costs, the Finance Committee find that the costs of preparation have been so reduced by the employment of the water process that they have been able greatly to reduce the price of insulin to the hospital. It was not easy to determine what the ultimate cost might be after further experience of the method, but it was decided to recommend an immediate reduction to something under 2*s.* per 100 clinical units. This price was arrived at after allowing for all overhead charges, cost of materials, salaries, and a margin of profit, which could be used for the purposes of continuing experiments with a view to the further improvement of technique and a still greater reduction in cost. This price is to be taken as the first instalment of the results to be expected from the new method, and it is confidently anticipated that a further substantial reduction in the price will be possible.

LISTER MEMORIAL FUND.—Sir Charles Sherrington, P.R.S., will unveil a monument to Lord Lister in Portland-place, London, W., on March 13th, at 11.30 A.M. Lord Hambleden will speak on behalf of the subscribers.

JOINT COUNCIL OF THE ORDER OF ST. JOHN AND BRITISH RED CROSS SOCIETY.—Dr. F. N. Kay Menzies has been appointed to succeed the late Sir Napier Burnett as Director of the Council's Department of Hospital and Medical Services, and will take up his duties on April 1st.

LEGION OF HONOUR.—The following appointments or promotions have just been made by the French Minister of Hygiene to the higher ranks of the Légion d'Honneur:—

Grand Officier.—M. Tuffier, chirurgien honoraire des hôpitaux.
Commandeur.—M. de Martel de Janville, chirurgien de Paris.
Officiers.—MM. Arrou, chirurgien honoraire des hôpitaux à Paris; Coussol, chef de bureau au ministère de l'hygiène; Hugenschmidt, docteur en médecine, à Paris; Henri Lévy dit Lévy-Bieg, docteur en médecine; Ménard, docteur en médecine.

OXFORD OPHTHALMOLOGICAL CONGRESS.—This congress will assemble at Keble College on the evening of Wednesday, July 2nd, and the meeting will be held on July 3rd, 4th, and 5th. On the morning of July 3rd a discussion on the General Principles of the Treatment of Convergent Concomitant Strabismus, with exclusion of the description of details of operations, will be opened by Dr. E. Landolt, of Paris, and Dr. Ernest Thomson, of Glasgow. The official dinner of the congress will take place on the evening of July 3rd. The Doyne memorial lecture will be delivered on the morning of Friday, July 4th, by Dr. T. Harrison Butler, the subject being Microscopy of the Living Eye, with especial reference to the Gullstrand Slit-lamp. Members intending to take part in the discussion or to contribute either papers or demonstrations are asked to notify the hon. secretary at their early convenience.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Friday, March 14th, in the Town Hall, Brighton, when discussions will take place on (1) the Schick Test and Immunisation against Diphtheria, to be opened by Dr. Duncan Forbes; (2) Ionisation in the Treatment of Ear Discharge, to be opened by Dr. Rutherford Cramb; (3) the Drainage of Brighton, to be opened by Mr. Harry Tillstone. The chair will be taken at 7.30 P.M. by Dr. Louis C. Parkes. The following will take part in the discussions: Drs. J. Cates, C. M. Fegen, A. Greenwood, F. C. Linton, H. P. Newsholme. On March 15th visits will be paid to the school clinic, school buildings and abattoir, and the pavilion, and to a farm to see the production of certified milk.

ROYAL COLLEGE OF SURGEONS IN IRELAND: CHARTER DAY DINNER.—This dinner was held in the College Hall last Saturday evening, March 1st, the President, Sir W. I. de C. Wheeler, in the chair. H.E. the Governor-General was the principal guest, and there were also present Lord Shaw of Dunfermline, the Lord Chief Justice of Ireland, the Recorder of Dublin, the Master of the Rolls, the Provost of Trinity College, the Vice-President of the Royal College of Physicians of Ireland, and Mr. James Sherren, surgeon to the London Hospital. The President, in proposing the "Prosperity of Ireland," referred to the progress of the country in the last year or two from disorder to order, and from instability to security. He said that he had been asked if it would be possible to accommodate in Dublin some 500 American surgeons, who were coming to study Irish methods of surgery. The progress of science was an essential condition to the prosperity of the country. The Governor-General, in his reply, took the opportunity of defending the medical service of the National Army against certain wanton charges of neglect or cruelty that had been brought against them. Into some of the more explicit of these charges he had personally inquired, and he had found that they were baseless. Sir F. Conway Dwyer proposed the "Learned Professions," and referred to the notable public services, in their several capacities, of Lord Shaw, of the Provost of Trinity College, and of Mr. Sherren. Lord Shaw, in his reply, expressed his friendly feelings towards Ireland, and his admiration for the recently framed Irish Constitution. Mr. Sherren entertained the audience with reminiscences of his early acquaintance with Ireland, when he followed the profession of sailor. The Provost of Trinity College, the Lord Chief Justice, the Vice-President of the College of Surgeons, and the Vice-President of the College of Physicians also spoke. At the end of the proceedings, the Governor-General, in proposing the toast of the "President," presented him, on behalf of the members of the Council of the College, with a handsome piece of plate. Sir William Wheeler's term of office comes to an end in June next. Owing to the regretted illness of his predecessor he has had to perform the duties of President for close on four years.

MEDICAL SOCIETY OF LONDON.—The annual dinner will be held at the Grand Hotel, Trafalgar-square, London, W.C., on Wednesday, March 12th, at 7.30 P.M.

MENTAL AFTER-CARE ASSOCIATION.—The annual meeting of this association will be held on March 11th at the Mercer's Hall, Ironmonger-lane, London, E.C., when Sir Charles C. Wakefield will preside.

SOCIETY FOR THE STUDY OF INEBRIETY.—The annual meeting of this society will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Tuesday, April 8th, 1924, at 4 P.M., when Dr. Bedford Pierce will open a discussion on Mental States in Alcoholism.

THE ANGLO-RUSSIAN MEDICAL COMMITTEE.—A committee has been formed under this title, which is also described as a "Public Health Contact Committee," its object being to obtain mutual information on medical and sanitary work and organisation in England and Russia. The scope of the committee has not yet been defined, but will be settled at the first meeting of the committee, which will take place immediately. Dr. L. Haden Guest, M.P., is acting as honorary secretary. One of the first questions for consideration will be the possibility of fighting epidemics on international grounds, the practical outcome of which would be the giving of assistance to Russia in the anti-malarial campaign.

Parliamentary Intelligence.

HOUSE OF LORDS.

THURSDAY, FEB. 28TH.

Lord MUIR-MACKENZIE, on behalf of the Government, introduced a Bill to consolidate the existing Health Insurance Acts.

TUESDAY, MARCH 4TH.

National Health Insurance.

The Government's Bill to consolidate the existing National Health Insurance Acts was read a second time.

HOUSE OF COMMONS.

TUESDAY, FEB. 26TH.

Small-pox in British and Indian Armies.

Mr. WHITELEY asked the Secretary of State for War how many cases of, and deaths from, small-pox occurred in the various commands of the British and Indian armies during the years 1921 and 1922.—Mr. STEPHEN WALSH replied: The following are the statistics asked for:—

British Army.

Command.	1921.		1922.	
	Cases.	Deaths.	Cases.	Deaths.
India	32	7	25	10
Iraq	18	4	6	Nil
Turkey	Nil	Nil	5	Nil
All other commands ..	Nil	Nil	Nil	Nil
Total	50	11	36	10

Indian Army.

Northern	25	2	No figures available.
Southern	13	1	
Eastern	8	Nil	
Western	5	1	
Total	51	4	

Report of Far Eastern Commission on Venereal Disease.

Viscountess ASTOR asked the Secretary of State for the Colonies whether he would consider the advisability of submitting to Parliament the report of the Far Eastern Commission of the National Council for Combating Venereal Diseases, including the Commission reports on Hong Kong, Singapore, and Colombo.—Mr. J. H. THOMAS replied: The document in question is not an official report, and its publication is a matter for the National Council for Combating Venereal Diseases. I regret that I should not feel justified in directing its publication at the expense of the State, but I have no doubt that the Council will readily afford facilities to any honourable Members who may wish to peruse the report.

Poor-law Administration.

During the debate on the action of Mr. Wheatley, the Minister of Health, in rescinding the Poplar Order made by Sir A. Mond in 1921, Dr. HADEN GUEST, Parliamentary Private Secretary to the Minister, urged the introduction of a human note into the administration of the Poor-law. There was, he said, every reason for taking children out of the control of the Poor-law and putting them under the control of the education authority. There was every reason for taking the administration of the Poor-law—infirmaries, parish medical services, and so on, and especially the large children's hospitals—out of the control of the Poor-law altogether and using them, with other medical services in the country, to form the basis of a really great public health and medical service. That, he added, could be done.

WEDNESDAY, FEB. 27TH.

Small-pox Cases from 1911 to 1920.

Lieut.-Colonel FREMANTLE asked the Minister of Health the number of cases of small-pox notified on an average for the years 1911 to 1920 and, respectively, in each of the last three years and this year up to date; and the proportion of infant or primary vaccinations to births in each corresponding period, this year excepted.—Mr. GREENWOOD (Parliamentary Secretary to the Ministry of Health) replied: The average number of cases of small-pox notified during the years 1911 to 1920 (civilians only) was 146·3 per year. The numbers of cases notified since 1920 have been as follows: In the year 1921, 315; 1922, 973; 1923, 2486; 1924 (up to Feb. 9th), 478. The figures for 1923 and 1924 are provisional. The proportion of children born during the years 1911 to 1920 who were vaccinated was 45·0 per cent. For 1921 the proportion was 38·3 per cent. The figures for 1922 and 1923 are not yet available.

London School of Hygiene.

Lieut.-Colonel FREMANTLE asked the Minister of Health when the charter of incorporation of the London School of Hygiene, founded through the munificence of the Rockefeller Trustees, would be sealed and published.—Mr. WHEATLEY replied: I hope that the charter of incorporation will be granted in the course of the next few weeks.

Compulsory Vaccination.

Mr. BLACK asked the Minister of Health whether, in view of the fact that in Leicester during 17 years up to the end of 1922 there was not a single death from small-pox, whilst the vaccination rate fell during the same period from 18·3 per cent. to 3·4 per cent., and that for the whole of England and Wales during the same period the total number of deaths had been 255, with a falling vaccination rate of from 73 per cent. to 38·3 per cent., he would bring in a measure to repeal the 1907 Vaccination Act, abolish all compulsion, and leave the question of vaccination to the discretion of the individual citizen.—Mr. WHEATLEY replied: I am considering the present position in regard to vaccination, but I am unable to give any promise to introduce legislation on this subject.

Removal of Advanced Tuberculosis Cases.

Mr. SOMERVILLE HASTINGS asked the Minister of Health whether he could give the number of persons suffering from advanced tuberculosis of the lungs who were living in the same overcrowded homes with, and infecting, their relations; and whether he intended to bring forward legislation for the compulsory removal, if need be, of such persons.—Mr. WHEATLEY replied: I regret that the information asked for in the first part of the question is not available, as regards the second part, this matter will be considered in connexion with any proposals for the amendment of the Public Health Acts.

THURSDAY, FEB. 28TH.

Mental Cases in Prisons.

Mr. STRANGER asked the Under Secretary of State for the Home Department whether he was aware that there were in prisons many inmates mentally and medically unfit confined in observation cells, but in charge only of the ordinary disciplinary officer; and whether, in future, he would arrange to have those men placed in charge of a medical prison orderly instead of a disciplinary officer.—Mr. RHYS DAVIES replied: The number of hospital officers at present available does not admit of this being done in every case, but the Prison Commissioners are making the best arrangements possible within the resources at their disposal and those resources are being steadily improved.

Hostels for Ex-Service Mental Patients.

Sir ELLIS HUME-WILLIAMS asked the Minister of Health (1) whether the hostels recently started for the reception of ex-Service mental patients were entirely distinct and apart from lunatic asylums; whether the hostels were provided with recreation grounds and games; and what medical staff was employed at each. (2) How many hostels, other than asylums, for the reception of ex-Service mental patients had been started, where they were situated, and how many men were now under treatment.—Mr. F. O. ROBERTS replied: Under the existing law I have no power to establish or control institutions for the treatment of pensioners

certified to be insane, except under powers vested in some existing licensee or local authority. As previously announced to the House, the Government has made special arrangements for a selected number of certified cases of a hopeful type likely to make progress under special treatment. Accommodation for 150 such cases is provided at the old manor, Salisbury, and for a further 300 at Kirkburton, a detached block at Storthes Hall Asylum, near Huddersfield. At the former institution there are two medical officers and in the latter three, in addition to the medical superintendent of the main asylum. In both institutions ample facilities are provided for recreation and games, and at the latter there is a welfare officer, whose special duty it is to look after the general welfare of the patients, apart from the purely medical treatment. As regards those mental cases which are not certifiable under the Lunacy Law, it has always been the policy of my department to provide special treatment and accommodation with a view to their complete recovery. To that end, the Ministry have given special training to a number of medical officers and established throughout the country neurological hospitals and clinics where skilled treatment on the most approved modern lines is provided. These efforts have, I am glad to say, met with conspicuous success, for instance, as is shown by returns for a recent quarter, the percentage of those patients discharged recovered or improved is about 70, while in one hospital devoted to the most serious cases, out of 134 patients treated during the year, 68 were discharged recovered, while of the remainder a number had shown considerable improvement. At all these hospitals full provision is made for the recreation, amusement, and occupation of these patients under a welfare officer. These hospitals, numbering 19, are situate at Edenhall, Edinburgh; Shotley Bridge, Gateshead; Oulton Hall, Leeds; Mossley Hill, Lancs; Maghull, near Liverpool; Harrowby Camp, near Grantham; Aston Court, Bristol; Bath; Fernbank, near Roehampton; Ewell, Surrey; Orpington, Surrey; Richmond, Surrey; Sidcup, Kent; Leopardstown, Co. Dublin; Saltash, near Plymouth; Romford, Essex; Craigavon, Belfast; Latchmere, Surrey; Rotherfield Court, Henley-on-Thames. The approximate number of beds is 3024. The number of men under treatment on Jan. 31st was 2772. The total number of medical officers dealing with the treatment of these cases is 67.

Medical Appointments in Prisons.

Sir MURDOCH MACDONALD asked the Under Secretary of State for the Home Department, in view of the opinion of Lord Justice Atkin's Committee on insanity and crime, and of the accompanying memorandum of the Council of the British Medical Association, whether the similar recommendations made by the Departmental Committee on Prisons in April, 1895, to the effect that candidates for medical appointments in prisons should be required to show that they had given special attention to lunacy, had ever been carried out; and would he furnish a return showing the experience in the treatment of insanity before appointments in prisons and criminal asylums.—Mr. RHYS DAVIES replied: When candidates are selected for the appointment of medical officers preference is always given to those who have had some experience of lunacy. Of the 24 whole-time medical officers now serving, 13 had asylum experience, and five had attended students' courses at asylums. As regards posts for part-time medical officers, these are filled by practitioners in the locality and preference is given, wherever possible, to those who have had special experience of lunacy. The medical superintendent of Broadmoor Asylum and his deputy had had asylum experience before their appointment.

Blind Pensioners.

Mr. GILBERT asked the Minister of Pensions the number of blind pensioners pensioned by his department; what was the average pension received by such pensioner; whether, if such pensioner was the inhabitant of a home or hospital for the blind, any deduction was made from the pension; and, if so, what amount.—Mr. F. O. ROBERTS replied: There are 1550 totally blinded officers and men all of whom are receiving pension from my department at the maximum rate. The amount paid in such varies according to rank and family, an unmarried private receiving pension at the rate of 40*s.* a week. Allowances for wives and children of married men are additional. These pensioners are cared for by St. Dunstans (or in Scotland by Newington House), and when they are in either of these institutions they receive allowances at the maximum rate of pension without any deduction.

Medical Examination of Air Force Candidates.

Lieut.-Colonel RUDKIN asked the Under Secretary of State for Air if he was aware that candidates for the Air Force, after they had successfully passed the necessary examinations, were reviewed by the medical authorities, and in some cases rejected; and, in view of the hardship created and the time and money wasted, would he take steps to ensure that the medical examination should be held prior to the written or oral examination.—Mr. LEACH replied: The answer to the first part of the question is in the affirmative. The possibility of holding the medical examination prior to the examination conducted by the Civil Service Commissioners was carefully considered recently, and the conclusion arrived at was that the disadvantages outweighed the advantages. I may add that this opinion was shared by the headmasters who were consulted by the departments. Parents and guardians are strongly recommended in the regulations to have their sons or wards examined by a medical practitioner or by a Royal Air Force preliminary medical board previous to their becoming candidates for commissions in the Royal Air Force, and full details of the medical standards are published in the regulations. If my hon. and gallant friend's question refers to candidates for aircraft-apprenticeships as well as to cadets, I may add that the same reasons for holding the educational examination first are applicable to their case.

TUESDAY, MARCH 4TH.

Harnett v. Bond.

Mr. COSTELLO asked the Prime Minister whether, in view of the evidence given before Mr. Justice Lush and the verdict of the jury and the observations of the learned judge in the case in which a Mr. Harnett was awarded damages amounting to £25,000 against two medical men for causing his confinement as a lunatic, he would without delay appoint a Royal Commission to inquire into the present lunacy laws and their administration, and the conditions under which persons alleged to be insane could under existing regulations be deprived of their personal liberty and confined in asylums or otherwise placed under detention.—Mr. COMYNS-CARR asked the Prime Minister whether his attention had been called to the verdict of the jury and observations of Mr. Justice Lush in the recent case of Harnett *v.* Bond and Adam in the King's Bench Division; and whether a Royal Commission would be appointed forthwith to inquire into the best means of preventing the state of affairs which appeared to prevail with regard to the law and administration relating to lunacy.—Mr. TURNER-SAMUELS asked the Prime Minister whether his attention had been called to the case of Harnett *v.* Bond and another in which on Wednesday a jury found that the defendant's doctors were guilty of wrongly detaining the plaintiff as an inmate of various asylums from Dec. 14th, 1912, to Oct. 15th, 1921, a period of nine years, that the evidence showed that the plaintiff was not of unsound mind on Dec. 14th, 1912, and that during the whole time from then he was fit to be at large; and whether he would immediately have a Royal Commission or other form of inquiry set up to inquire into the administration of the Lunacy Acts in this particular, and especially in regard to the sufficiency of the steps that were taken by the Commissioners in Lunacy and other responsible persons, and the means that were available to an inmate to prevent persons from being detained in lunatic asylums when they ought not to be so detained.—Mr. RAMSAY MACDONALD replied: The proceedings in this case closed as lately as Friday last, and the shorthand notes have only just been received. The Government have not yet had time to give proper consideration to the difficult and complex issues raised, but prima facie it would appear that there is a case for full inquiry, and the Government are fully prepared to consider the setting up of an appropriate body to undertake such an inquiry. I may add that I understand the question of an appeal is under consideration.

Dr. SPERO asked the Under Secretary of State for the Home Department whether, having regard to the verdict of Harnett *v.* Bond and others, and to the damages awarded, his department proposed to accept any responsibility in the matter.—Mr. GREENWOOD replied: I have been asked to reply, and would refer the hon. Member to the answers given by the Prime Minister on this subject.

On the motion for the adjournment of the House, Mr. TURNER-SAMUELS called attention to what he termed the maladministration of the lunacy laws, which, he said, was creating a very definite and scandalous menace to personal liberty. The facts that had recently been revealed in the case of Harnett *v.* Bond proved conclusively that in many cases people who were sane were being immured within the walls of an asylum without having any right to be there at all. There were, of course, urgent and dangerous cases which called for immediate action, but full safeguards should be taken to prevent improper detention. He had personally gone carefully into all the facts connected with certification, discharge, and medical inspection, and he had ample evidence that in every head and department of the administration of the lunacy laws, not only was there neglect but there was also danger to personal liberty. He urged the Government to set up immediately a Royal Commission to look into the bad conditions prevailing in the administration of the lunacy laws.

Mr. GREENWOOD (Parliamentary Secretary to the Ministry of Health) said that the Prime Minister had given a most sympathetic answer to a question that afternoon, and having regard to the fact that an appeal had been lodged, the matter was sub judice. He understood that the appeal might be heard at an early date, after which the Prime Minister would consider the advisability of having the inquiry started at once.

Miners' Phthisis.

Mr. GAVAN-DUFFY asked the Secretary for Mines if he would state what were the terms of reference he had made to the health advisory committee respecting the death of an iron-ore miner named Wilkinson from miners' phthisis; when the members of the health advisory committee were likely to receive the reference which he had made to them; and was he aware that it was now nearly 12 months since any meeting of the health and safety committee of the metalliferous mining industry had been held.—Mr. SHINWELL replied: The facts reported by my hon. friend about the death of Wilkinson were brought before my health advisory committee at their meeting last week, and are being considered by them as part of their general inquiry into dangers from dust. There was no formal reference. I am aware that the Health and Safety Subcommittee of the Metalliferous Advisory Committee has not met for some time; but this has not prevented health questions affecting the industry being dealt with by my health advisory committee, of which the chairman of the subcommittee in question is a member.

Miners' Welfare.

Mr. BATEY asked the Secretary for Mines the total amount paid into the welfare scheme and the total amount paid out for approved schemes; and how many of the approved schemes included pit-head baths.—Mr. SHINWELL replied: The total amount paid into the Miners' Welfare Fund, together with interest on investments, amounted at Feb. 29th, 1924, to £2,608,180 0*s.* 6*d.* The total amounts actually paid out at that date for approved schemes were £837,779 10*s.* 6*d.* from district funds and £60,372 12*s.* 2*d.* from the general fund, but the total amounts allocated to such schemes were about £1,570,500 and £86,000 respectively. The number of approved schemes which include pit-head baths is eight.

Mothers of Weak Intellect.

Mr. G. OLIVER asked the Minister of Health whether, in order to ascertain the magnitude of the question of children born in our Poor-law institutions of mothers of weak intellect, he would issue instructions for the necessary information to be collected.—Mr. WHEATLEY replied: I will consider my hon. friend's suggestion.

The Lister Ward.

Mr. J. BROWN asked the Secretary for Scotland whether, in view of the great interest and value of the Lister ward in the Royal Infirmary of Glasgow, and the strong pleas for its preservation received from all over the world, he would consider the advisability of taking immediate means to ensure that demolition would not be begun until an inquiry could be made.—Mr. ADAMSON replied: I have no authority to intervene in this matter.

KENT AND CANTERBURY HOSPITAL.—The supporters of this hospital have adopted a scheme for collecting subscriptions, known as the Propaganda Committee's Hospital Box Scheme. The third annual meeting of this committee was recently held at Canterbury. The number of honorary representatives, officials, and stewards is over 800, and the subscribers number over 12,000. In order to eliminate the competition of those towns and villages which have to support local hospitals, it is proposed to bring all these institutions under the scheme, and to give patients the choice of hospital, all patients to be paid for by the fund. In order to effect this object representative committees will be appointed in every town and district, controlled by a representative central committee. The annual report states that the total receipts for 1923, including the special ambulance fund, were £6833. On account of box subscriptions they had paid to the hospital £5500, while £258 had been paid direct on account of entertainments, &c. The working expenses totalled £312. On the Ambulance-Garage Fund the total receipts were £885, the cost of the ambulance being £679. The income of the hospital for 1923 was £13,348 and the expenditure £13,289, leaving a credit balance of £59. The number of in-patients admitted during the year was 1483, against 1290 in 1922, and out-patient attendances were 21,918, against 19,905; 736 in-patients were admitted on box subscription certificates, their total cost being £5547. The total cost per head amounted to £7 10*s.* 9*d.* for in-patients and 1*s.* 8*d.* for out-patients.

Appointments.

DUNSCOMBE, N. D., M.B., B.Ch., D.P.H. Camb., L.M.S.S.A., has been appointed Assistant School Medical Officer, Somerset County Council (Bath area).

GILLILAND, H., M.B., Ch.B. Edin., Medical Officer, Staines Workhouse.

St. Thomas's Hospital: HOPE-SIMPSON, J. W., M.B., B.Ch. Camb., YATES, H., M.R.C.S., L.R.C.P. Lond., CREED, R. S., M.B., B.Ch. Oxf., BERRIDGE, W. C. M., M.R.C.S., L.R.C.P. Lond., JEFFERY, A. L. P., M.B., B.S. Lond., WALFORD, A. S. H., M.B., B.Ch. Camb., WEBB-PEPLOE, M. H., M.B., B.Ch. Camb., METCALFE, G. A., M.B., B.Ch. Camb., Casualty Officers and Resident Anæsthetists; DYSON, A. D., M.R.C.S., L.R.C.P. Lond., MURRELL, E. B., M.R.C.S., L.R.C.P. Lond., COOPER, G. K., M.B., B.Ch. Camb., PALMER, H. M., M.R.C.S., L.R.C.P. Lond., Resident House Physicians; STORY, A. G., M.B., B.Ch. Camb., Resident House Physician (for Children); LAUTRÉ, M. A., M.R.C.S., L.R.C.P. Lond., LUPTON, C. A., M.R.C.S., L.R.C.P. Lond., BRIGGS, T. E., M.R.C.S., L.R.C.P. Lond., WILLIAMS, L. G., M.R.C.S., L.R.C.P. Lond., Resident House Surgeons; ALLAN, F. G., M.R.C.S., L.R.C.P. Lond., Resident Orthopædic House Surgeon: PEARCE, T. V., M.B., B.S. Lond., JONES, B. H., M.R.C.S., L.R.C.P. Lond., Resident House Surgeons for Ear and Throat respectively; ALLEN, H. S., M.R.C.S., L.R.C.P. Lond., Senior Obstetric House Physician: CROCKFORD, A. L., M.B., B.Ch. Camb., Junior Obstetric House Physician; PENMAN, G. G., M.R.C.S, L.R.C.P. Lond., Senior Ophthalmic House Surgeon: BATTSON, A. A., M.R.C.S., L.R.C.P. Lond., Junior Ophthalmic House Surgeon; CAVENAGH, J. B., M.B., B.Ch. Oxf., NEILSON, D. F. A., F.R.C.S. Eng., DOYLE, A. F., M.R.C.S., L.R.C.P. Lond., BARRON, H. T., M.D. Lond., FACEY, R. V., M.R.C.S., L.R.C.P. Lond., DOGGART, J. H., M.R.C.S., L.R.C.P. Lond., MARRINER, H. I., F.R.C.S. Edin., JARRATT, W. O. C., M.R.C.S., L.R.C.P. Lond., TURNEY, H. F., M.B., B.Ch. Oxf., COOKE, A. M., M.B., B.Ch. Oxf., WALKER, E. G. L., M.R.C.S., L.R.C.P. Lond., WEAVER-ADAMS, E. R., M.R.C.S., L.R.C.P. Lond., HALLIWELL, C. C., M.R.C.S., L.R.C.P. Lond., MITCHESON, G. F. L., M.B., B.Ch. Oxf., FIRTH, E. K. A., M.R.C.S., L.R.C.P. Lond., DUNN, W. H., M.R.C.S., L.R.C.P. Lond., THORP, K. W., M.R.C.S., L.R.C.P. Lond., STARKEY, R. S., M.R.C.S., L.R.C.P. Lond., STEVENS, A. L. B., M.B., B.Ch. Oxf., DUNN, W. H., M.R.C.S., L.R.C.P. Lond., RICKMAN, J., M.B., B.Ch. Camb., Clinical Assistants.

Certifying Surgeons under the Factory and Workshop Acts: LEWIS, G. M., L.R.C.P. Lond., M.R.C.S. (Peasenhall); HOCKEN, D. F., M.B., B.S. Durh. (St. Blazey); KENNEDY, F. H., M.B., B.S. Durh. (Pershore); ELAM, J. E. (Barnet); ADAM, J. C., M.B., Ch.B. Edin. (Forres).

Vacancies.

The Chief Inspector of Factories, Home Office, London, S.W., announces a vacant appointment at Ayr.

Births, Marriages, and Deaths.

BIRTHS.

LAPAGE.—On March 2nd, at Forest Row, Sussex, the wife of F. Claud Lapage, M.R.C.S., L.R.C.P., of a daughter.
WEBB-JOHNSON.—On Feb. 27th, at "Cricklewood," East Sheen, the wife of Dr. Cecil Webb-Johnson, of a daughter.

DEATHS.

BICKERSTETH.—On Feb. 29th, at Bournemouth, Robert Alexander Bickersteth, F.R.C.S., of Borwick Lodge, Hawkshead, aged 61 years.
CLARK.—On Feb. 26th, at Greenbank, Street, Somerset, Ann Elizabeth Clark, M.D., in her 80th year.
FITZGERALD.—On March 1st, after a long illness, at his residence, Cappawhite, Co. Tipperary, Ireland, Joseph FitzGerald, M.D.
JAMIESON.—On Feb. 27th, at Cromwell-road, S.W., Thomas Hill Jamieson, M.B.E., M.D., M.R.C.P. Edin., aged 50.
REID.—On Feb. 27th, at Okement, Okehampton, Inspector-General Walter Reid, M.D., R.N. (retired), aged 83 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 10th.

WAR: at 5 P.M.
Paper:
Flight-Lieutenant H. L. Burton, R.A.F.: Psychomotor Responses in Relation to Flying (with particular reference to an apparatus invented by Flight-Lieutenant G. H. Reid, D.F.C., R.A.F., for Determining Flying Reaction Times).
Demonstration:
Flight-Lieutenant G. H. Reid, D.F.C., R.A.F.: Apparatus for Determining Flying Reaction Times.
To be followed by a discussion.

Tuesday, March 11th.

THERAPEUTICS AND PHARMACOLOGY: At 4.30 P.M.
Paper:
Prof. W. Storm van Leeuwen (Leyden): A theory of Asthma, with special reference to the Influence of Climate.
To be followed by a discussion in which Mr. Frank Coke and others will take part.

PSYCHIATRY: At 8.30 P.M.
Paper:
Dr. Sullivan: The Relation of Alcoholism to Insanity and to Crime.

Wednesday, March 12th.

SPECIAL DISCUSSION: At 5 P.M.
On the Possible Substitutes for Cocaine. Sir William Hale-White (President of the Society) in the chair. Opener: Dr. H. H. Dale. Prof. W. E. Dixon, Prof. C. S. Gibson, Mr. T. B. Layton, Sir Maurice Craig, Mr. Foster Moore, Mr. E. Watson-Williams, and others will also speak.

Thursday, March 13th.

NEUROLOGY: At 8 P.M. (At the National Hospital for the Paralysed and Epileptic, Queen-square, W.C.)
Clinical Meeting.

Friday, March 14th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)
Cases:
Dr. C. F. T. East: Diabetes Insipidus with Unusual Features.
Dr. D. Firth: Congenital Absence of Sternal Portion of Pectoralis Major.
Short Papers:
Dr. T. Stacey Wilson: (1) Three Cases where Nervous Symptoms were due to the Dilatation of the Deep Thigh Veins; (2) Temporary Loss of Memory, similar to that in Double Personality, due to Colon Disturbance.

OPHTHALMOLOGY: At 5 P.M. (At the National Hospital, Queen-square, W.C.)
Clinical Meeting.
Members of the Section have been kindly invited to tea at 4.30 P.M. by the Committee of the Hospital.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, March 10th.—8.30 P.M., Discussion on the Disturbances of the Nervous System in Hyperpiesia. To be introduced by Dr. Batty Shaw, followed by Sir Humphry Rolleston, Prof. Ernest Starling, Prof. W. Russell, Dr. James Collier, Dr. F. M. R. Walshe, Dr. Geoffrey Evans, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
TUESDAY, March 11th.—5 P.M., Lieut.-Colonel Glen Liston, C.I.E.: The Plague. (First Milroy Lecture.)
THURSDAY.—Second Milroy Lecture.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.
MONDAY, March 10th, to Saturday, March 15th.—BETHLEM ROYAL HOSPITAL. Course in Psychological Medicine: Tues. and Sat., 11 A.M., Dr. Porter Phillips and Dr. Thomas Beaton: Psychoneuroses.—CHELSEA HOSPITAL FOR WOMEN. Daily: Operations, &c.: Mon., 5 P.M., Mr. Rivett: Extra-uterine Gestation; Tues., 2 P.M., Mr. Bonney; Wed., 2 P.M., Mr. Dodd: Ovarian Cysts; Thurs., 9.30 A.M., Mr. Provis: Gonorrhœa in Women: Fri., 2 P.M., Mr. Comyns Berkeley: Carcinoma of the Uterus; Sat., 11 A.M., Mr. Goodwin: Pathological Demonstration.—THE ROYAL FREE HOSPITAL. Wed., 5.30 P.M., Dr. Heald: The Medicinal Uses of Ultra-violet Light.—ROYAL NORTHERN HOSPITAL, in conjunction with the CENTRAL LONDON OPHTHALMIC HOSPITAL, NORTH-EASTERN FEVER HOSPITAL, and ROYAL CHEST HOSPITAL. Special Intensive Course (second week). Further particulars can be obtained from the office 1, Wimpole-street, W. 1.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE: FEBRUARY–MARCH, 1924.
CLINICAL LECTURES AND DEMONSTRATIONS.
MONDAY, March 10th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Clinical Types of Paraplegia: Dr. Aldren Turner.
TUESDAY, March 11th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Cerebral Vascular Disease: Dr. Adie.
THURSDAY, March 13th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., The Neuroses: Dr. Hinds Howell.
FRIDAY, March 14th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Neurosyphilis: Dr. James Collier.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.
MONDAY, March 10th.—12 noon, Disseminated Sclerosis: Dr. J. G. Greenfield.
The fee for the Course, including Pathology, is £5 5s. For those who hold Perpetual Tickets the fee is £3 3s.

COURSE OF LECTURES ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.
WEDNESDAY, March 12th.—12 noon, Cerebral Cortex: Association Systems.
THURSDAY, March 13th.—12 noon, Sympathetic Nervous System: Dr. Kinnier Wilson.
The fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.
WEDNESDAY, March 12th.—3.30 P.M., Ocular Palsies and Disturbances of Ocular Movement: Mr. Leslie Paton.
The fee for this Course alone is £5 5s. If taken in conjunction with the general Post-Graduate Course the fee is £3 3s. All applications should be sent to the Secretary, Medical School.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.
Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.
J. G. GREENFIELD, Dean of Medical School.

ST. THOMAS'S HOSPITAL, Albert Embankment, S.E.
(In the Governors' Hall.)
THURSDAY, March 13th.—5 P.M., Dr. J. A. Murray: Cancer. (Last Lecture.)

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.
THURSDAY, March 13th.—4 P.M., Dr. Still: Abdominal Distension.

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, March 12th.—4.30 P.M., Mr. C. E. Shattock: Carcinoma of the Colon.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, March 10th.—10 A.M., Surgical Registrar: Surgical Pathology. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Bishop Harman: Eye Dept.
TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Throat, Nose and Ear Dept. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Dept.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
FRIDAY.—10.30 A.M., Dr. Pritchard: Medical Wards. 12 noon, Mr. Endean: Venereal Diseases. 2 P.M., Mr. Sinclair: Surgical Out-patients.
SATURDAYS.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose and Ear.
Daily, 10 A.M. to 6 P.M. Saturdays, 10 A.M. to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE. (Prince of Wales's General Hospital.)
(At 4.30 P.M.)
MONDAY, March 10th.—Dr. A. J. Whiting: Sinus Arrhythmia.
TUESDAY.—4 P.M., Mr. J. Howell Evans: Hydrocele.
WEDNESDAY.—Dr. J. Browning Alexander: Pulmonary Emphysema.
THURSDAY.—Mr. H. W. Carson: The Early Diagnosis of Cancer of the Stomach.
FRIDAY.—Dr. C. E. Sundell: Bottle Feeding.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
TUESDAY, March 11th.—5 P.M., Dr. Gray: The Tuberculides.
THURSDAY.—5 P.M., Dr. Fox (Chesterfield Lecture): Cutaneous Syphilis.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, March 10th.—(At the Children's Hospital.) Mr. Morrison: The Diagnosis of Chronic Appendicitis in Children.
TUESDAY.—(At the Southern Hospital.) Mr. Douglas-Crawford: Surgical Cases.
WEDNESDAY.—(At the Northern Hospital.) Mr. Rawlinson: Pyelitis.
THURSDAY.—(At the Stanley Hospital.) Dr. Oram: Demonstration of Radiographs.
FRIDAY.—(At the Royal Infirmary.) Mr. Kennon: Surgical Cases.

VICTORIA UNIVERSITY OF MANCHESTER MEDICAL SCHOOL.
FRIDAY, March 14th.—5.30 P.M., Prof. J. C. Brash: The Growth of the Jaws and Palate.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, March 11th.—4.15 P.M., Dr. G. R. Murray: Significance of Changes of Blood Pressure.

MANCHESTER BABIES' HOSPITAL POST-GRADUATE LECTURES.
FRIDAY, March 14th.—5.30 P.M., Dr. Nesta Wells: Infection in Infants' Wards.

SALFORD ROYAL HOSPITAL LECTURES.
THURSDAY, March 13th.—4.30 P.M., Dr. C. E. Jenkins: The Bacteriology of Joint Infections.

UNIVERSITY OF SHEFFIELD POST-GRADUATE LECTURES. (At 3.30 P.M.)
FRIDAY, March 14th. (At the Royal Hospital.)—Mr. Townrow: Demonstrations of Oral Cases.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, March 12th.—4 P.M., Dr. G. B. Dixon: Some Aspects of the Tuberculosis Problem in an Industrial City.

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	£2 2 0
	Six Months	1 1 0
	Three Months	0 10 6
ABROAD	One Year	2 10 0
	Six Months	1 5 0
	Three Months	0 12 6

Subscriptions not paid in advance are charged out at the published price of 1*s.* per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER, THE LANCET Offices, 423, Strand, London, W.C. 2.

Notes, Comments, and Abstracts.

WHERE DOES MENTAL HYGIENE BEGIN? *

AN AMERICAN VIEW.

BY L. VERNON BRIGGS, M.D. RICHMOND, VA.,
DIRECTOR OF THE MASSACHUSETTS SOCIETY FOR MENTAL HYGIENE.

ONLY two decades ago we were all working for the better housing of the mentally ill and for humane care of them both inside and outside institutions. We then felt that this was all that we could ask for them, and its accomplishment was a great step forward. Conditions in many institutions—overcrowded as they were—savoured more of the prison than of the hospital. The meagre staffs were only able to look after physical ills called to their attention by ward nurses or by patients themselves. The majority of patients only saw the physician as he passed hurriedly through the wards in which they spent their days and nights. In some of the hospitals no occupation was known other than the polishing of floors and ward, and kitchen work which had no therapeutic value. Exercise in the open consisted of a walk around the grounds under the direction of attendants, the patients being strung out in files. The staffs did little, if any, scientific work, in most of the hospitals, and few hospitals had a laboratory. Operations which had to be performed by visiting surgeons necessitated bringing the patient into one of the ward rooms or doctors' offices, where tin pails and vegetable pans were used for sterilising the instruments over ordinary stoves. This state of affairs persisted as late as 1912.

Outside the institutions the mentally ill received little consideration. Taken from their homes, from boarding places, or from the street when they showed signs of mental aberration, they were thrust into police stations or city gaols and there kept, often for days, before being transferred to a hospital and treated as sick individuals. This condition also obtained in Massachusetts until 1912. So the first step for a generation towards the really humane care of the mentally ill, which was then the height of our ambition, was only reached a decade ago.

Psychopathic Hospital Idea.

The psychopathic hospital idea in this country started as early as 1906 with the Psychopathic Hospital at the University of Michigan. Prior to this an observation ward was established in 1890 in the Philadelphia Hospital, and about the same time Dr. Adolph Meyer developed an observation department in his hospital at Kankakee, Ill. In 1896 the Psychiatric Institute on Ward's Island, N.Y., was established, and under Dr. Meyer psychiatric wards were opened in connexion with the Institute in 1902. Bellevue Hospital and Kings County Hospital in New York also had wards for psychiatric cases. Following the establishment of the Psychopathic Hospital at the University of Michigan in 1906, there was established in 1912 a psychopathic hospital in Boston, at first a department of the Boston State Hospital but since made an independent unit. The following year, 1913, the Phipps Psychiatric Clinic was started at Baltimore under Dr. Meyer, in connexion with the Johns Hopkins Hospital Medical School and Hospital. With the psychopathic hospital idea came more scientific care and treatment within the institutions, although little progress was made outside of institutions or in the community. Pathological laboratories were established in many of our State hospitals and in our general hospitals scientific studies were made of mental disease; but there was no centre of scientific research or direction until the psychopathic hospital idea was established, when another very important objective was reached.

Social Service.

With the establishment of the psychopathic hospital idea came social service. In Massachusetts, following the lead of Richard Cabot with his social service as a part of the Massachusetts General Hospital out-patient department, the Boston Dispensary established a similar service, and there the first social service workers were trained in mental clinics. Comparative statistics for three months without, and for three months with, social workers in the mental clinic of the Boston Dispensary showed that that service prevented the commitment of many early cases by following up early mental treatment, as directed by physicians, and obtaining results beyond the routine treatment of clinical service, and by improving social conditions, thus preventing

* Read at a Conference of Social Work, held at Stamford, Conn., U.S.A.

other members of the same family or of the locality from similar breakdowns. Social service after-care also prevented the return to the hospitals for the insane of many discharged cases. Social case work, follow-up work, research work, educational work were the functions outlined by Miss Hannah Curtis for the social service. So important has this work become that there is now a Training School for Social Workers at Smith College in Northampton, an institution of which the success is established. The requirements are two summers of study at Northampton and nine months of practice in some social agency or hospital social service under the school's supervision—a total course of 13 months. The graduates are prepared for various branches of social case work and community service, especially in psychiatric cases.

Out-patient Clinics.

With the beginning of the better care of the mentally ill two decades ago, there was established an out-patient clinic at the Boston Dispensary for mental cases. There was also a neurological clinic; the staffs of these clinics referred cases to each other, but worked separately. It was my privilege to be elected head of the mental out-patient clinic at the dispensary soon after it was established in 1899, which position I held until 1912, when I became a member of the State Board of Insanity.

Social workers trained in the mental department at the Boston Dispensary proved a valuable aid to the physicians and a blessing to the patients; it revealed the patient's environment, which was often the cause of his breakdown; social agencies soon learned to refer to the mental clinic many cases which heretofore they had not been able to help. With the opening of the Psychopathic Hospital in Boston and the establishment of its out-patient clinic a good deal of the work done at the dispensary was transferred there, which greatly broadened the field, for the Psychopathic Hospital soon took cases from the courts and also from agencies outside of the city. Thus what is now known as mental hygiene began in Massachusetts two decades ago; out-patient departments for mental cases increased so fast that within a little over ten years there were nearly 40 functioning in the State of Massachusetts, and this number has been maintained to the present time.

Education in Mental Hygiene.

The spread of the psychopathic hospital idea and its influence on the community soon began to be felt. The community was becoming educated in mental hygiene. Its influence in court procedure was first made manifest in the establishment of Dr. W. Healy's work in the courts of Chicago in 1909 with delinquent and psychopathic individuals, especially children. This influence has spread to many courts throughout our country, from Boston to Seattle, where to-day one may obtain a liberal education in mental hygiene. With the establishment of the industrial accident boards, mental hygiene became a factor in industry. Many large firms and corporations employ nurses and doctors to instruct their employees in mental hygiene and also to detect the first symptoms of nervous and mental breakdown, correct them, or direct these patients into channels where they may receive early treatment.

Another progressive step taken in mental hygiene tending towards prevention was its introduction into the schools and the application of its teachings. Massachusetts passed a law in 1919 whereby school physicians and school nurses, properly trained, were to be employed for the purpose of studying, assisting, or treating children whose backwardness or delinquency showed they needed special instruction, medical care, or a change in their environments. Teachers are now directed to report to the school physician or school psychiatrist the names of pupils who are backward or show abnormality in their work in any direction, and also of the true delinquent. Psychiatrists then make special examinations and the nurse visits the home.

In order to prevent these children from keeping others back special classes are formed for them. Teachers experienced in the instruction of retarded minds develop these children at least to the point of taking care of themselves, if possible; for the first time in history such children have a fair chance, for they stood no chance whatever when competing with children who had been endowed with much greater powers of assimilating knowledge.

It soon developed that many of the causes of backwardness could be removed if intelligently handled and scientifically treated. Environmental conditions at home, bad habits, glandular difficulties, improper or insufficient feeding—one or several of these often affecting the same child—when removed or cured, enabled that child to take its place in the school and in the world.

So it was in the courts. The child who had been brought into the municipal courts charged with destroying property, or setting fires, with bad habits or being stubborn, or perhaps guilty of petty stealing, sometimes taught by his father or mother, and who had never had an opportunity of knowing right from wrong, was set right, and often made into a valuable citizen, as the result of Dr. Healy's work and, later, of the work of other psychiatrists appointed to the courts. Mental hygiene, which began a few years ago with the child in school and with the early delinquent, has gone a step further and now is to begin with the baby.

Education of the Very Young.

Dr. Douglas A. Thom has organised clinics in Boston with a view to correcting habit formation in babies and very young children, and also ascertaining the cause of any convulsions or other abnormal phenomena which may be observed by those in charge of these babies in the hospitals and in the community. He says, in relation to the behaviour problem of the nervous child, that many of these conditions can be traced to a failure on the part of the individual to adapt himself to his environment, even in the years of childhood, and that we are beginning to feel that more and more frequently the individual is the victim of his environment rather than of his heredity. It is not unreasonable to presume that if there is a group of cases belonging to the economic and social failures which have their beginning in the mental conflicts of childhood, and these conflicts can be discovered at 5 years instead of 13, much will have been accomplished for the child and for all those with whom he is to come in contact. There are certain fundamentals necessary to the mental development of every human being that are more in evidence during childhood that in any other period of life. Those of particular importance because of their utility are: plasticity, suggestibility, imitativeness, and love of approbation. It has been figuratively stated in one way or another that man is extremely complex—that he has very great capacity for modification, and that his period of mobility lasts longer than in other animals. Thus the plasticity of the early years of life should be utilised to its limit in an effort to develop habits which will later serve the individual in good stead.

Not only is it important to study the material with which we are dealing, so far as the child is concerned, but it is quite necessary to know by whom, and under what conditions, this material is being used. The immediate environment, the home and its occupants and surroundings are what go to make up the mental atmosphere in which the child lives.

Education of the Mother.

Much of the child's early life is, or should be, spent with the mother. Her influence cannot be over-estimated, but all too frequently it is not as healthy as we might hope. The mother may be worn out by household cares; she may be striving to supplement the family budget by a few hours of work outside, when she should be resting or in bed; or she may be pleasure-loving, avoiding her duty, having turned her responsibility over to the nursemaid for so many pieces of silver.

Again, we may find that a mother with the most excellent intentions may be over-solicitous. Too frequently she is emotionally unstable; what is condoned to-day may be punished to-morrow; and in spite of ability to adjust rapidly, the child finds it difficult or impossible to follow a consistent line of conduct. There is no situation so pathetic for both mother and child as that of the mentally defective mother who is doing her best, yet failing, and recognising her own failures.

In order to ascertain just what the home situation is and what factors are to be utilised or combated, a trained social worker is employed to make investigation and to see that the doctor's directions are fully understood and are being carried out. It is important not to make mere interviews out of these visits, but to use workers who are not afraid to get down to the social and intellectual level of their hostess, as far as possible. The factors which are likely to contaminate the mental atmosphere of the child can frequently be determined in this way and referred for advice and assistance to the doctor, minister, teacher, social agency, or whatever source to which it seems advisable to turn.

Dr. Thom, feeling that the foregoing principles might be utilised to advantage, has organised "habit clinics" in connexion with the Baby Hygiene Association, to deal with those children who in the pre-school age—that is, between 2 and 5—are developing undesirable habits, and to determine, in so far as possible, the basis of these habits and to institute measures which will tend toward their correction.

Mental hygiene should be inculcated as soon as the child is capable of forming habits, when any abnormal, physical, or mental symptoms appear. The attack on mental disease at this early period, and the following of it through the schools with scientific purpose will, it is hoped, result in our not being called upon to build as many "monuments of resignation," as the State hospitals have been called, for housing and feeding thousands of hopeless derelicts, who represent an immeasurable loss of intelligence to the community. But, as Dr. Thom says, the existence of clinics for children of pre-school age do not require justification.

No claim is here made that there is any relation between the undesirable habits of childhood and psychoses of later life; yet it is not difficult to see how closely these infantile reactions resemble the psycho-neurotic manifestations of adult life, and that a fundamental lack of inhibitions may be a dominating characteristic in a criminal career.

STERILISATION OF RUBBER GLOVES.

Dr. W. Lutzmoer, of Werro, in Estland, writes to *Ars Medici* (1924, ii., 42) to recommend, as a result of nine years' experience, the following method of sterilising rubber gloves: "Put on the perfectly sound unsterilised gloves, and wash the gloved hands with soft soap and water once or twice, then smear the gloves carefully with the following solution, which should be poured liberally on a swab—Rp. iodi puri 2·0 gm., spiritus vini (70 per cent.) 200·0. With this method I have even with laparotomy never seen fever or infection, besides which the gloves last a very long time."

CIVIL SERVICE BONUS.

THE Ministry of Health, in a circular (No. 477) dated Feb. 28th, has informed local authorities that the review on March 1st of Civil Service bonus will be on the basis of an average cost of living figure of 80—i.e., on the same basis as obtained during the six months commencing March 1st, 1923. In the case of salaries over £500 a year the bonus will still be subject to the special percentage deductions specified in 1921. In view of the increase of this bonus the range within which bonus may be paid by local authorities to those of their officers whose remuneration is subject to the Minister's sanction is correspondingly increased.

"POPULAR FALLACIES EXPLAINED AND CORRECTED."

Mr. A. S. E. Ackermann, B.Sc., has spent some 22 years in collecting the material for this book, now in its third edition, in which 1350 popular ?allacies are subjected to scientific scrutiny and thereby refuted. The subject-matter, divided into 25 fields of error, comprises nearly the whole domain of human knowledge, from football to astronomy. The author has taken great pains to obtain his information from specialists and authoritative sources, to which he adds touches of humour in many instances. The section entitled "Ourselves" deals with popular misconceptions as regards our bodies and our diseases, and should prove of interest and value to the practitioner who finds himself faced with age-old superstition or modern pseudoc-scientific notions in the course of his ministrations. The book, which is published by the Old Westminster Press at 12*s.* 6*d.*, is well annotated, and contains a preface by Sir Richard Gregory, D.Sc. F.R.A.S. An excellent addition to the reference shelves.

THE DIARY OF A FIELD AMBULANCE.

WE have received a little volume[1] which is a kind o *journal intime* of the 44th Field Ambulance, contributed to by all ranks, and gives perhaps a truer picture of the real life of the army than many more pretentious official histories. It touches lightly on matters of strategy, and adds but little to medical knowledge, but it does succeed in conveying a vivid impression of the life of a divisional medical unit, and of the joys and sorrows of the men who bore the burden and heat of the day. The 44th Field Ambulance was a unit with a very highly developed esprit de corps—"We were, after all, just one large family, and the loss of one after another struck hard at us." It was this spirit which helped them to win a tribute from two infantry commanding officers of the 14th Division during the Battle of the Somme—"At all times officers and men of the 44th Field Ambulance loyally answered to the very many calls made upon them, and carried out their work under heavy fire, regardless of personal danger."

The history of the unit is traced from its formation at Aldershot in September, 1914, its training, its embarkation for France in May, 1915, and through the various battles in which it took part with the 14th Division—"the first unit of the new army to be seriously engaged." Ypres, Hooge, Sanctuary Wood, Arras, the Somme, Telegraph Hill, Glencorse Wood, Inverness Copse, Passchendale, St. Quentin, and the dark days of 1918, Messines and the final Flanders offensive, all tell the tale of its activities. The list of killed and wounded and the record of honours won make an impressive tribute to the work done by a small unit (one of many such), less than a company of infantry in size, and there are many moving passages in the book. Besides this, however, there is a light-hearted, almost impish record of amusing incidents in the unit's career, and sport has quite a considerable share in the chronicle. "Jerry lost the war by concentrating on such silly things as Hymns of Hate. We won it by playing and laughing and doing things in the spirit of the 18th Londons when they dribbled their football across No Man's Land in the attack on Loos." In the creation and functioning of such units as this the Army Medical Service achieved a triumph of organisation of which it can be justly proud.

The volume is illustrated with photographs, plans and some delightful pen-and-ink sketches, and there is a very interesting diagram showing the method of evacuation of wounded from the front line to the base. It is altogether a book which should appeal to everyone who took part in the medical services during the war, particularly those who served in similar units, and the 44th Field Ambulance is to be congratulated on its enterprise in compiling this excellently produced record.

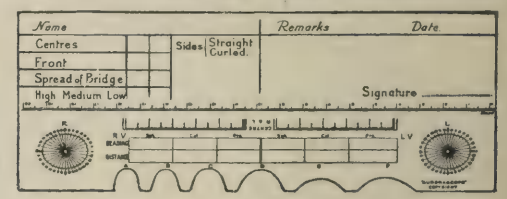
[1] With the Forty-Fourths. Being a Record of the Doings of the 44th Field Ambulance (14th Division). London: Spottiswoode, Ballantyne and Co. Pp. 83. 5*s.*

BAYER "205" AND FOURNEAU "309."

ALTHOUGH nothing definite has yet been announced regarding the composition of Bayer "205," an approximate graphic formula appeared in the *British Medical Journal* of Sept. 23rd, 1922. The *Journal* of the Society of Chemical Industry for Feb. 29th now calls attention to the probable identity of Bayer "205" and Fourneau "309." The latter is said to be a symmetrical urea of meta-amino-benzoyl-meta-amino-paramethylbenzoyl 1-naphthylamine-4.6.8-trisulphonate of sodium. This formula closely resembles that given by Dr. H. King in the annual report of the Medical Research Council for 1921.

AN OCULIST'S FRAME-FITTING PRESCRIPTION CARD.

A DIFFICULTY confronting the general practitioner is to have a ready and easy system of giving instructions to the optician in the matter of supplying properly fitting spectacles. This is important in prescribing astigmatic, bi-focal lenses, &c., which, if ill-fitting, often distort the vision, irritate the patient, and defeat the object of even the best corrections. It applies to the general practitioner who, perhaps, living far away in the country or the Colonies, has taken up refraction work. I have devised a simple Frame-fitting and Prescription Card (see figure) which, when doubled on itself,



gives a measurement of 8 in. long and 1½ in. broad, marked as is customary with opticians, in millimetre scale. The lower section shows a series of usual standard fittings of the bridge of the nose, marked A, B, C, D, E, F. The corrected vision being determined and the axis of the cylinders recorded, the bridge of the nose is measured by fitting on the semi-oval cut-outs, the size being determined according to the letter A, B, C, D, E, or F. Further, a statement as to the height of the bridge is suggested such as *high*, *medium*, or *low*, and is noted on the upper section of the prescription card. To mark off the optical centres (a most important point) the card, folded on itself, showing two oblong spaces, right and left, is placed on the eyebrows, the patient being directed to look straight in front and the pupillary centre is recorded on this special space by the mark X. The final step is to note the width of the forehead or front on the long measured scale. In carrying out the proceedings suggested, no numerical calculations are necessary and no special skill is required. It is not intended that the work of the optician should be usurped, but their services are frequently out of reach of their would-be clients.

The cards have been made for me by the Aurorascope Co., Ltd., Fulwood House, Fulwood-place, Holborn, W.C.

London, W. HENRY DUTCH, M.R.C.S. Eng.

LEEDS WORKPEOPLE'S HOSPITAL FUND.

THE thirty-seventh annual report shows an income of £37,639 for 1923, an increase of £4462, compared with 1922. Workshops—the main source of the income—showed an income of £2539, the workshop contributions in 1923 reaching £27,839. Apart from the maintenance of the convalescent home—a balance of over £28,000 was available for distribution among the local medical charities. Of this sum the Leeds General Infirmary received £18,000, the Public Dispensary and Hospital for Women and Children each £2500, the Maternity Hospital £900, and smaller institutions less sums in proportion.

The Relationship OF SOME HÆMOLYTIC DISORDERS TO PERNICIOUS ANÆMIA.

BY P. N. PANTON, M.B., B.CH. CAMB.,
DIRECTOR OF HALE CLINICAL LABORATORIES;
A. G. MAITLAND-JONES, M.D., M.R.C.P. LOND.,
SECOND ASSISTANT, MEDICAL UNIT, LONDON HOSPITAL;
AND
GEORGE RIDDOCH, M.D. ABERD., M.R.C.P. LOND.,
FIRST ASSISTANT, MEDICAL UNIT, LONDON HOSPITAL.

(From the Medical Unit and Clinical Laboratories of the London Hospital.)

THE object of this paper, which is supplementary to one previously published by us in THE LANCET,[1,2] is to call attention to some examples of obscure hæmolytic disorders and to discuss their relationship to pernicious anæmia. Some of them present rare and hitherto almost undescribed conditions. All appear to have the common factor of internal hæmolysis, but since they differ in other respects we present them in a short series of small groups.

EVIDENCE OF INTERNAL HÆMOLYSIS IN PERNICIOUS ANÆMIA.

It is important at this stage to state the evidence on which we assume that internal hæmolysis takes place in pernicious anæmia and the morbid states we are about to consider. We realise that as yet proof of internal hæmolysis in pernicious anæmia does not rest on an entirely satisfactory basis and we hope later to put it to experimental test; but for the present we accept it as a working hypothesis.

The generally accepted evidence for this view is the serious diminution of red cells, in the absence of external blood loss, associated with signs of greatly increased red cell formation as shown by hyperplasia of the red marrow and the presence of abnormal and immature red cells in the peripheral circulation. Additional evidence is afforded by increased pigment excretion in the urine, coloration of the blood serum, the deposition of free iron in the viscera, splenic enlargement, and red-cell phagocytosis. The interpretation of these data as evidence of internal hæmolysis has received some experimental support. Bunting [3] found that in rabbits anæmia secondary to severe and repeated hæmorrhages was accompanied by the blood and bone marrow picture of secondary anæmia, but that if the circulating red cells were attacked by a hæmolytic toxin, ricin, or saponin, the changes produced in the blood and red marrow were similar to those of pernicious anæmia. Bunting favoured the view that the circulating toxin acted upon both the red cells and the marrow. McMaster [9] and Haessler, however, found that if rabbits were repeatedly bled and at the same time given subcutaneous injections of hæmoglobin the resultant anæmia was accompanied by marked proliferation of the red marrow, and they concluded that the factor determining this proliferation was the presence in the body of hæmoglobin, or its precursors, in excess of the amount which could be utilised by the marrow already existing.

CLINICAL CASES.

First Group.

The first group of cases comprises two, the main features of which are the blood changes of pernicious anæmia, jaundice, and hæmoglobinuria.

CASE 1.—A dock labourer, aged 33, became an in-patient at the London Hospital in December, 1905. Two years and eight months previously he had begun to feel tired and languid, and five months previously had passed what he took to be blood in his urine. This apparent hæmaturia was repeated a few days later, and he was admitted to St. Bartholomew's Hospital, where a diagnosis of "jaundice and hæmoglobinuria" was made. The hæmoglobinuria soon ceased and the patient, having improved, was discharged. About three months later his weakness returned and he was admitted to the London Hospital. On examination the skin was lemon-tinted, the spleen was felt three fingers-breadth below the costal margin, and his temperature was raised to between 101° and 103° F.; there was marked pyorrhœa and no wasting. Whilst in hospital the patient had an attack of hæmoglobinuria with no relation to cold, which was followed by sudden pain in the chest and hæmoptysis suggestive of pulmonary infarction. This again was followed by thrombosis in the right posterior tibial and left internal saphenous veins. During the following three to four years this patient was admitted to the London Hospital altogether on five occasions. During the intervals between the admissions he returned to his work. In February, 1909, he was seen by one of us for the first time and his blood on examination gave the following readings: Red cells 1,321,000 per c.mm., colour index 0·9, marked morphological changes in the red cells with numerous megaloblasts and a relative lymphocytosis. The patient was obviously jaundiced and the serum contained bile pigment. The urine was of a port-wine colour with a deposit of golden-brown pigment and hæmolysed red cells, and showed the spectrum of oxyhæmoglobin. The Wassermann reaction (W.R.) was negative.

This patient was examined by one of us on several occasions during his remissions and while engaged upon his work as a dock labourer. During all this time he was strikingly anæmic, with a hæmoglobin percentage of about 20. Admitted for the last time in January, 1910, with a sore throat and an exacerabtion of oral sepsis, his general condition and blood state were found to be much the same. But acute septicæmia developed and the patient died. Post mortem, the characteristic changes of pernicious anæmia were found in addition to those of acute sepsis.

CASE 2.—A bricklayer, aged 38, was admitted with an apparently similar condition into the London Hospital in June, 1918. He gave an eleven years' history of anæmia and eight years' history of periodic attacks of hæmoglobinuria, which occurred without exposure to cold. Examined on admission, this patient was a well-developed muscular man, very anæmic and slightly jaundiced; he stated that he became jaundiced whenever his urine became red, which occurred about once every four to eight weeks. The spleen was not palpable. Whilst in hospital he developed thrombosis of his right median basilic and cephalic veins. His urine contained hæmoglobin and granular casts, but no red cells. No attack of severe hæmoglobinuria occurred during his stay in hospital. The serum was tinged with bile, and examination of the blood gave the following readings: Red cells 1,150,000 per c.mm., colour index 0·9, marked morphological changes in the red cells with many megaloblasts; there was also a leucopenia of 2600 cells per c.mm. with a relative lymphocytosis. The fragility of the red cells was normal and the W.R. negative. This patient was discharged after a month's stay in hospital and died two years later, after constant ill-health and inability to do any work. No post-mortem examination was carried out.

It is evident that these two patients were strikingly similar, in that they were males of about the same age with a clinical condition and blood state suggestive of pernicious anæmia, but differing from it in the following points: The occurrence of attacks of hæmoglobinuria and thrombus formation in superficial veins, the presence of marked jaundice, which is a very rare event in pernicious anæmia, and the long duration of the illness, 8 years and 13 years respectively.

The question arises as to the category in which these two cases are to be placed. Are they examples of so-called paroxysmal hæmoglobinuria or of pernicious anæmia with hæmoglobinuria? With regard to the first alternative, it has been our experience that in paroxysmal hæmoglobinuria, alterations in the blood count other than those of a possible slight secondary anæmia are not found. With regard to the second alternative, the history and clinical state in these two cases differed, as has just been mentioned, from those in pernicious anæmia, and further the occurrence of hæmoglobinuria in this disorder is extremely rare; we have been able to find in the literature only one reference [8] to its presence, although Minot [10] refers to it as occurring occasionally.

There is a third possibility. Are these two patients examples of the acquired form of hæmolytic icterus with hæmoglobinuria occurring during the hæmolytic phases? Various examples of this condition have been recorded, and lately Giffin [4] has described under

the title of "Hæmoglobinuria in Hæmolytic Jaundice" a case which resembles to a considerable extent the two cases we have described above. Giffin considered his case, a woman of 32, to be an example of hæmolytic jaundice, but in the absence of splenic enlargement or of any familial history of the condition the diagnosis rested mainly on two estimations of the red cell fragility. On both occasions hæmolysis commenced at 0·5 per cent. saline as contrasted with a normal at 0·42 per cent. The red cell changes resembled those of pernicious anæmia. We should consider the red cell fragility in Giffin's case as less marked than is the rule in typical examples of hæmolytic icterus, and the same criticism applies to other cases quoted by Giffin in his article. In one of our cases in which the fragility was examined it was found to be normal. We revert later to the relationship between pernicious anæmia and hæmolytic icterus, as well as to the difficulty in distinguishing between occasional atypical cases which appear to occupy a position intermediate between the two conditions. For the present we prefer to place the two cases here described in a separate category.

The difference, however, between this condition and pernicious anæmia is apparently one of degree only, the phases of slow blood destruction responsible for the relapses of pernicious anæmia being accentuated by short sharp bursts of blood destruction in which the quantity of hæmoglobin liberated is so large that it is excreted as such in the urine.

Second Group.

The second group of cases concerns two subjects of arseniuretted hydrogen gas poisoning observed by us. AsH_3 is a well-recognised agent of internal hæmolysis and there was no doubt as to the diagnosis in these cases, but they are included here because of the strong clinical resemblance which they bear to the preceding group.

CASES 3 and 4.—Two men employed in a chemical works, their duty being to supervise a mixture of zinc and sulphuric acid in an open vessel. Both these materials were subsequently found to contain arsenic, which in the sulphuric acid amounted to 0·066 per cent. Shortly after leaving work on one occasion both men had sudden epigastric pain, vomited, and passed urine like blood. On examination two days later they were found to be drowsy, delirious, markedly jaundiced, and profoundly anæmic. The urine contained a large amount of hæmoglobin. The blood showed the red cell and hæmoglobin changes of pernicious anæmia, both normoblasts and megaloblasts being present. Bile pigment was present in the blood, but not in the urine. Both patients made a rapid and uneventful recovery. On admission they stated that they were employed at a lead works, but the association of jaundice, anæmia of the primary type, and hæmoglobinuria was sufficiently indicative of the cause of their condition.

Such cases, though well known to occur, are rarely met with in the practice of the London Hospital. They serve as a valuable object-lesson of the effect of inhaling a powerful and rapidly acting hæmolytic poison.

Third Group.

The third group is represented by one case, the detailed account of which is in course of publication by one of us in conjunction with Dr. J. H. Sequeira. We give an outline of the more important points.

CASE 5.—A butcher, aged 32, first seen by one of us in 1910, giving one year's history of skin irritation, worse on exposure to cold, and six months' history of a rash and loss of hair. On admission to the London Hospital the skin of the limbs and trunk was black, the colour of a negro's. The face and hands were a dark yellowish brown. The patient was quite bald. The blood state was that of pernicious anæmia with 1,530,000 red cells per c.mm., hæmoglobin 28 per cent., and colour index 0·9. Numerous normoblasts and megaloblasts were present. The urine was normal and, with the exception of well-marked oral sepsis, no other physical signs of disease were found. Previous to this illness the patient described himself as a perfectly healthy man. No drugs, such as arsenic or silver, had been given him by his doctor. The patient was given arsacetin, and during the next month his blood condition was that of an improving case of pernicious anæmia. The blood continued to improve, but reverted to the secondary anæmic type, the count four months later being 4,350,000 red cells per c.mm., with a colour index of 0·5 and very occasional normoblasts were found. During this period the colour of the skin became markedly lighter.

The patient was readmitted for observation in 1921 and again in 1922. Since 1910 he has suffered from anæmia to a degree which has prevented him from following his occupation. His appearance has entirely altered and he does not suffer from any skin irritation. He may now be described as a grey-haired lemon-tinted man. In 1921 his blood showed a severe anæmia with a low colour index of about 0·5 and numerous normoblasts on several examinations. In 1922 the colour index was again usually low but varied (0·27 to 0·71), and the red cell changes were extreme. On one occasion 322 normoblasts and 13 megaloblasts were seen while counting 200 leucocytes (white cells 5800 per c.mm.) The patient is still alive and apparently in much the same condition.

We would describe this man as an example of severe internal hæmolysis of very long duration—from 1910 to 1923—in which the broken-down blood pigment instead of being deposited in the internal viscera as in pernicious anæmia, or voided in the urine as in the previous group of cases, is stored in the skin—at any rate in part. This abnormality in pigment distribution is associated with a hæmolytic process of extreme chronicity suggesting that we are considering here a condition allied to, but differing from, pernicious anæmia.

The syndrome exemplified by this patient appears to be of great rarity and unlike that of hæmochromatosis associated with diabetes. Mosse,[11] in a paper dealing with melanosis of the skin in pernicious anæmia, recently described a somewhat similar case in a woman, but in his case, which was of an acute type, he came to the conclusion that the pigmentation was arsenical. In Case 5 arsenic as a cause was investigated and excluded.

Fourth Group.

The fourth group comprises a variety of conditions usually classified under the term of "paroxysmal hæmoglobinuria." We describe here two examples only:—

CASE 6.—A wood carver, aged 17 years, was admitted to the London Hospital in 1912 with a six months' history of pain in the back and a seven weeks' history of "blood" in the urine appearing only after exercise and disappearing when he lay down. The urine passed by the patient when lying down was perfectly normal, but after he stood up it contained a heavy cloud of albumin. After he took half an hour's walk it became claret-coloured, gave a marked guaiac reaction, presented the spectrum of oxyhæmoglobin, and deposited a heavy sediment of broken-up red cells. The patient's serum was of normal colour in the intervals between the attacks, but during the attacks was faintly tinged with hæmoglobin. The sequence of events leading up to hæmoglobinuria did not seem to be in any way dependent upon exposure to cold, but was proved on several occasions to follow upon exertion. The erect posture led to the passage of albumin, mild walking exercise to a mild degree of hæmoglobinuria, and more strenuous walking exercise to severe hæmoglobinuria with the passage of porter-coloured urine. The W.R. was tested on several occasions and was either negative or incompletely so. The boy had no other physical signs of disease and no stigmata of congenital syphilis. The blood count showed a mild degree of anæmia with a slight inflammatory leucocytosis. The patient was given 10 c.cm. of horse serum subcutaneously and the following day walked for two miles. His urine at the end remained clear and free from albumin. Three days later the hæmoglobinuria returned after exercise and 10 c.cm. more serum was given. The urine again remained clear after exercise, but after a period the patient relapsed again. Four injections of horse serum were given altogether, and after the final injection the patient was observed over a period of several weeks, during which he took sufficient walking exercise to wear out his boots, and except for the very occasional presence of a slight amount of albumin the urine remained normal. No further treatment had been given, and now, 11 years later, the patient is perfectly well and has been free from attacks in the interval.

The points of interest in this case are the suggested relationship between the postural albuminuria of adolescence and paroxysmal hæmoglobinuria, the definite dependence of the attack upon exercise and not upon exposure to cold, the probable absence of a syphilitic origin, and the cure, first temporary and finally complete, consequent upon the injection of horse serum.

The second example of the fourth group is described mainly as a contrast to the first.

CASE 7.—A Jew, aged 40, was quite well up to the age of 31, when he married; during his honeymoon he passed "blood" in his urine for the first time. He had several mild attacks of this nature and five years later, after bathing, he got a severe attack of hæmoglobinuria, followed by deep jaundice which lasted for several days. During the next four years he experienced numerous severe attacks of the same nature and always after exposure to cold. On examination during an attack his urine was the colour of porter, and contained methæmoglobin and the débris of red cells. He was deeply jaundiced and his serum was strongly bile-tinged. His blood showed a very mild degree of anæmia with a slight inflammatory leucocytosis and the fragility of his red cells was normal. He denied syphilitic infection, but his W.R. was unfortunately not obtained. Treatment with horse serum had no beneficial effect.

This man presented the more usual type of hæmoglobinuria definitely associated with exposure to cold in contrast to the previous case in which the attacks followed exercise in the erect posture. Case 6 was given horse serum on the supposition that some inhibitory substance, which might in normal man prevent the possible hæmolytic action of the chemical products of muscular activity, was absent in his case. Whether the supposition was right or wrong the result of giving the horse serum was dramatically successful. In Case 7 the serum was quite ineffective.

Paroxysmal hæmoglobinuria is defined by Chester [7] and Basil Jones as "a chronic disease, due to syphilitic infection, manifesting itself in recurrent paroxysms of hæmoglobinuria and in characteristic constitutional symptoms. The blood of patients who suffer with this disease contains in latent form a specific hæmolysin which becomes active when the blood is chilled and produces the attacks." In a recent article Hannema[5] and Rytma have described the reaction of Donarth and Landsteiner by which hæmolysis is brought about on exposure of the red cells to ice-box temperature. They also mention the experiments of Hymans van der Bergh and Hymans showing the influence of a carbonic acid gas atmosphere in favouring hæmolysis, and the later work of Widal, Abram, and Brissaud on the mechanism of the hæmolytic process in paroxysmal hæmoglobinuria.

But while something has been learnt of the hæmolytic process in these rare states, it is probable, and the two cases which we describe strengthen the probability, that the agent involved may vary in the different cases met with and that the underlying syphilitic factor may not be constant. However this may be, the usual type of paroxysmal hæmoglobinuria following remotely upon syphilis and nearly upon exposure to cold bears little resemblance to the usual type of pernicious anæmia. Yet the first group of cases (Nos. 1 and 2) described in this paper provide examples as near as may be intermediate between the two conditions, and in considering one state of internal hæmolysis it is necessary to consider other conditions associated with the same process. It does not, however, appear to us probable that the essential underlying factors in pernicious anæmia and paroxysmal hæmoglobinuria are in any sense identical.

Fifth Group.

The fifth group is represented by only one case.

CASE 8.—A chauffeur, aged 33, admitted to the London Hospital in February, 1922, with the history that he was quite well up to 12 years before admission. He then began to feel weak and noticed that his colour became yellow. After continuing more or less in this state for four years he was admitted to a hospital in London, yellow tinged and with a palpable spleen. Splenectomy was performed for "acholuric jaundice." The fragility of the patient's red cells was stated to be normal before and to be increased after operation. He said that after the operation he lost his yellow colour and was quite well for three years, except that every summer he felt a little weak and languid. At the end of the three years he again became yellow, and periodic attacks of sore tongue occurred, usually in the summer months. A year after the return of his symptoms he began to have difficulty in walking, which gradually got worse, so that a year before he came under our observation in the London Hospital he was bed-ridden and had lost control over his bladder and rectum.

On examination after his admission to the London Hospital this patient was a well-nourished man with a lemon-yellow tint. His heart and lungs were normal, and beyond the scar of his operation the abdomen was also normal. He complained of persistent numbness in his upper and lower limbs, most marked in the feet and hands. He was intelligent without any obvious mental abnormalities. His fundi and cranial nerves were normal. His upper limbs showed no weakness, local wasting, or disturbance of tone, but they were slightly ataxic. There was marked weakness of his lower limbs with wasting, especially below the knees, and gross ataxia. Tone was not apparently affected. Biceps-jerks were brisk and equal, knee-jerks present and equal, and ankle-jerks absent, while his plantar responses were extensor. Sensibility* to cottonwool and to pin-prick was diminished over both lower limbs, but elsewhere was perfect. Postural sensibility was greatly diminished in the toes of both feet and to a slight extent in the fingers of both hands. There was frequency of micturition with defective control over the bladder and bowel.

Repeated examinations of his blood showed, during his six months' stay in the London Hospital, gross anæmia, the red cells varying from 600,000 per c.mm. to 3,000,000 per c.mm., with a high colour-index varying from 0·8 to 1·1. There were extreme morphological changes in the red cells and megaloblasts were very numerous. The serum was bile-tinged, but the resistance of the red cells to hæmolysis was normal. A fractional test-meal showed a complete absence of HCl and the W.R. in the blood was negative. The patient stated that his mother had five sisters and two brothers; one of the former had an enlarged spleen, was yellow, and died at an early age; and another died of "pernicious anæmia." In addition, one of his mother's brothers was admitted to the Prince of Wales's Hospital, where a diagnosis of "pernicious anæmia" was made and confirmed by the blood picture.

On his discharge from the London Hospital he was transferred to a local infirmary, where he died 16 months later and about 14 years after the onset of his illness. A post-mortem examination was not obtained.

The diagnosis in this case would appear to rest between pernicious anæmia and acholuric jaundice, and if we confine ourselves to these alternatives the evidence favours that of pernicious anæmia. The normal fragility of the red cells, the typical blood count, the achylia, the presence of subacute combined degeneration of the cord, and the history of a sore tongue all support this view. The most striking feature in the case and the one which raises any doubt in the question of diagnosis is the occurrence of three other examples of the same condition in the family. Familial pernicious anæmia has been recorded by Bartlett,[2] Patch,[13] and Minot [10] and, though rare, seems well established.

The familial occurrence of pernicious anæmia appears to us of the greatest importance in any consideration of the ætiology of the condition. A familial incidence places before us two alternatives in regard to ætiology. Either we have to consider the familial type as being due to a different cause, or we have to find a cause capable of producing the disorder in more than one member of the same family. The first alternative, that the familial type has a different ætiology, receives some support from a consideration of the case described here, in that certain features usually absent in pernicious anæmia were present—namely, jaundice, enlargement of the spleen sufficient to suggest splenectomy, advanced cord changes,* and a very chronic course of some 14 years. Any one of these features may be present in pernicious anæmia, but none of them commonly, and the combination of them added to the familial history suggests a different ætiology in the familial variety.

The other alternative—to find a satisfactory ætiological explanation for the occurrence of the disorder either in a single individual or in more than one member of the same family—presents great difficulties. The most popular conception of the ætiology of pernicious anæmia is that a hæmolytic poison is manufactured in the intestinal tract as the result of abnormal bacterial action. This might result from either the entry of abnormal bacteria or an upset of the balance of the normal intestinal flora.

* The relationship of subacute combined degeneration of the cord to pernicious anæmia is being made the subject of a special study, the results of which we hope to publish in the near future.

If the former explanation is adopted, it is difficult, if not impossible, to understand why contacts, other than members of the family, should not sometimes develop pernicious anæmia. The second explanation is attractive, and presupposes as its essential basis some persistent alteration, congenital or acquired, in the bacterial environment. It has been claimed that achylia is the primary abnormality in pernicious anæmia, and Hurst[6] has recently suggested that familial achylia, which is known to occur, is a complete explanation of the appearance of familial pernicious anæmia. But the observation, also quoted by Hurst, that 4 per cent. of normal individuals have achylia is strong evidence against this view; for the incidence of achylia in the general population being so high and that of pernicious anæmia so low the chances against any small group of individuals with achylia presenting three or more examples of pernicious anæmia would be so great as to imply that some other factor was involved.

Whatever the ætiology of pernicious anæmia may ultimately prove to be, the fact that the disorder is occasionally familial is suggestive, and a close study of members of affected families seems to be called for.

HÆMOLYTIC ICTERUS AND APLASTIC ANÆMIA.

In addition to the small groups of disorders described here there are two conditions, of which we have seen several examples, and to which attention should be directed in any discussion upon the relationships of pernicious anæmia. We refer to hæmolytic icterus and aplastic anæmia. Although in both these states internal hæmolysis occurs, the important underlying factors in them—namely, the red cell fragility of hæmolytic icterus and the red marrow destruction of aplastic anæmia—are absent in pernicious anæmia. Yet, as we have seen, cases are met with in which the diagnosis between pernicious anæmia and hæmolytic icterus may be difficult, as in a case recently described by Parkes Weber.[15] In the last nine cases of hæmolytic icterus seen at the London Hospital the colour-index was 1·0 or over in one or more of the blood examinations made in eight cases, and 0·5 in one case. Nucleated red cells were present in four cases and in one case normoblasts were numerous and megaloblasts were also found. Such a blood picture closely resembling that of pernicious anæmia is only to be expected in cases of internal hæmolysis. Conversely the continued production of immature and imperfect cells in pernicious anæmia might lead to the appearance of fragile erythrocytes. The fragility of the red cells in pernicious anæmia is usually normal or less than normal, but we have occasionally found it to be slightly increased. The fragility of the red cells in hæmolytic icterus is usually very much greater than the normal, but occasionally the difference may not be marked, and in such cases the condition is, in our experience, more often the acquired form of hæmolytic icterus than the congenital and familial variety. We infer that although pernicious anæmia and hæmolytic icterus are different states, it may not always be easy or possible to distinguish them during life. Aplastic anæmia, as we have observed the condition when it follows poisoning by a known chemical agent, such as trinitrotoluene, presents a blood picture by which the disorder may readily be recognised. When the ætiological factor is unknown typical examples of the disorder may also be met with, but not infrequently states are found which appear to be intermediate between pernicious anæmia and aplastic anæmia. Such states may represent examples either of pernicious anæmia presenting a subnormal degree of marrow regeneration or of aplastic anæmia in which marrow destruction is less complete than usual and hæmolysis is more excessive.

THE COMMON FACTOR OF INTERNAL HÆMOLYSIS.

As we have already stated, we, for the present, assume that internal hæmolysis is a pathological process common to all the disorders described in this paper, diverse though they are in many respects in their symptomatology and course. It is this feature which links them together and brings them into relationship with pernicious anæmia, because while the essential factor underlying this disorder is a subject of both conjecture and dispute, there is fairly general agreement that the predominant morbid process is destruction of red cells within the body.

The occurrence of this red cell destruction has, indeed, been recently called into question by certain workers, and notably by Ashby[1] and by Whipple.[16] Ashby puts forward the suggestion that the increased activity of the bone marrow in pernicious anæmia may be only apparent. She grants that the stimulus to red cell production causes an increase in the number of dividing cells, but she suggests that some factor is present which retards the rate of division, the net result being an increased red marrow area with a decreased cell output. Hæmosiderin deposition she regards as evidence only of failure to utilise sufficiently quickly the iron released in a normal rate of blood destruction.

Ashby's experimental evidence in support of this view was based on the results obtained from the transfusion of Group IV. blood into patients with pernicious anæmia belonging to other blood groups. The elimination of Group IV. corpuscles was watched by diluting the recipient's blood, after transfusion, with Group IV. serum and noting the number of corpuscles that remained unagglutinated. In four patients with pernicious anæmia examined over a long period by Ashby no evidence of rapid destruction of the transfused red cells was found. In two other patients, however, the elimination of the transfused blood appeared to be remarkably rapid.

Ashby's observations are, by the nature of the methods employed, subject to considerable experimental error. She appears to assume that the addition of Group IV. serum to blood of another group will agglutinate all of the red cells of that group, but this we have never observed to be the case. An examination of her protocols, moreover, shows that after a transfusion of only 500 c.cm. of Group IV. blood the foreign cells were estimated to form in many instances from one-fourth to almost the whole of the total cells. We have ourselves by means of large and frequently repeated transfusions raised the red cell content of a patient suffering from pernicious anæmia from under 1 million per c.mm. to approximately 5 millions in a fortnight. Yet two or three weeks later the red cell count was below 1 million again. The natural presumption is that the transfused red cells had been destroyed. In some of Ashby's cases the hæmolytic process was active during the period of observation, in others it was not and that is the common experience in this disorder.

Further criticisms of Ashby's deductions have been made by Wearn,[14] Warren, and Ames, and seem to be pertinent.

Whipple elaborates a novel scheme of normal pigment metabolism in which he suggests that possibly all pigment construction units pass through the stage of a "pigment complex" which is called upon either to construct hæmoglobin or bile pigment or to discharge urobilin or urochrome and that bile pigments are derived in part only from hæmoglobin. Whipple further suggests that a patient with pernicious anæmia having only one-fifth the normal number of red cells excretes twice or three times the normal amount of stercobilin, and that if stercobilin is a complete index of blood destruction the patient must regenerate his total red cell mass every three days instead of the supposed normal of 30 days.

Whipple prefers to explain the observed facts in pernicious anæmia by supposing an over-production of pigment associated with a deficiency or disorder of red cell stroma material, and he mentions hæmochromatosis as a condition in which no evidence of hæmolysis exists. But this does not appear to us to affect the question since it is not denied that an abnormal metabolism, retention, or distribution of pigment may occur without hæmolysis. Whipple's interesting paper is, as he himself points out, mainly speculative, and it appears to us to have more value as a contribution to pigment metabolism than as an

argument against increased destruction of red cells in pernicious anæmia.

That an increased production of pigment may occur in pernicious anæmia and that all the stercobilin in the fæces may not be derived from hæmoglobin is possible, but it seems to us to be more reasonable to account for the associated diminution of red cells in this disorder by the assumption of an increased red cell destruction for the reasons indicated by us at the commencement of this paper.

EXPLANATION OF VARIED CLINICAL PICTURE.

But before internal hæmolysis can be accepted as the pathological process common to all the disorders here discussed it is necessary to offer a satisfactory explanation for the wide variation in the clinical pictures presented. This, indeed, is our main purpose in this paper and is an attempt to elucidate the mechanisms underlying the production of those abnormal blood states, usually regarded as distinct entities, in which, whatever their ætiology may be, destruction of the red cell or its precursor is the predominant feature. There are two processes that appear to us to be of great importance in determining the clinical picture.

(1) *The Main Incidence of the Lesion.*—When the site of the lesion is chiefly in the circulating blood the red cell is distorted or destroyed in its mature state and hæmoglobin is liberated. To compensate for this deficiency increased production of new red cells occurs, and if the destructive process is prolonged there is consequent proliferation of the red marrow. Examples are paroxysmal hæmoglobinuria, in which red cell destruction is of short duration, and pernicious anæmia, in which the process is more chronic. When the lesion lies mainly in the bone marrow its consequences are more serious, for parent and immature cells are destroyed with resulting diminished regenerative capacity corresponding in amount to the extent of the damage. These cells do not, of course, contain hæmoglobin, and hæmoglobinuria, icteric tinging of the skin, and deposition of free iron in the viscera are absent. This occurs in aplastic anæmia. It may happen, however, and probably not infrequently, that the destructive process is not so specific in its incidence, but either progresses simultaneously in the circulating blood and bone marrow, or begins in one situation and extends to the other. Inability to categorise certain cases as pernicious anæmia or aplastic anæmia is the occasional experience of most investigators. Another group is represented by hæmolytic icterus where at least one link in the pathological complex constituting the lesion seems to be a lowered resistance of the red cell stroma to abnormal noxious influences or ordinary wear and tear. This defect may be congenital or acquired.

(2) *Rapidity of the Pathological Process.*—A second important factor in determining the evolution of the complaint is the rate and duration of the destructive process. When the process is acute, as in arseniuretted hydrogen gas poisoning (Cases 3 and 4), all the phenomena of rapid red cell disintegration appear—drowsiness, delirium, jaundice, hæmoglobinuria, and profound anæmia. If the dose is sufficiently large the patient dies. A less severe although still acute effect is evident in paroxysmal hæmoglobinuria. In pernicious anæmia, on the other hand, the process is characteristically slow, but phases of more rapid destruction are common and account for the relapses. Sometimes these are acute and in Cases 1 and 2 the paroxysmal attacks of jaundice, hæmoglobinuria, and aggravation of the anæmia were doubtless due to sudden exacerbations of the destructive process. The obvious explanation of the prolonged course, sometimes lasting many years, in certain cases of pernicious anæmia is that red cell destruction is less extensive and unusually prolonged.

The patients, Nos. 2 and 6, described above, were admitted to the London Hospital under the care of Dr. Robert Hutchison, and we are much indebted to him for his help in their investigation.

THE METABOLIC CHANGES ASSOCIATED WITH X RAY AND RADIUM TREATMENT.

BY E. C. DODDS, M.B., B.S., B.Sc. LOND.,
CHEMICAL PATHOLOGIST TO, AND LECTURER IN BIOCHEMISTRY IN, THE MIDDLESEX HOSPITAL;
AND
J. H. DOUGLAS WEBSTER, M.D., M.R.C.P. EDIN.,
PHYSICIAN IN CHARGE OF THE RADIOLOGICAL DEPARTMENT, AND LECTURER IN RADIOLOGY, MIDDLESEX HOSPITAL.
(*From the Biochemical Department, Bland-Sutton Institute of Pathology, and the Department of Radiology, Middlesex Hospital, London.*)

THE chief interest at present in the consideration of the causation of radiation "sickness" or toxæmia centres on the more essential biochemical changes resulting from radiation. Many of the other factors which have been discussed can only be subsidiary or rarely operative, such as gas poisoning in X ray rooms, or high induced voltage of patients having X ray treatment. Psychical causes also can only be at work to a limited extent. But in temporary depression of the functions of the kidneys, or in a toxæmia from the definite organic products of proteolytic or autolytic changes (possibly anaphylactic), or in inorganic disturbance from acidosis or other metabolic changes, the essential causes are now being sought. It was the recent hypothesis of Andersen and Kohlmann that roentgen sickness is "like an acute uræmia," which prompted the following investigation, the results of which are here given in a greatly condensed form. It was felt that should the condition be anything "like an acute uræmia" a study of the basal metabolism would show definite and characteristic changes. If it proved not to be uræmic other characteristic changes might be found which would enable radiation sickness or toxæmia to be grouped with the analogous metabolic changes also producing "sickness" when present in sufficient intensity: anæsthesia, diabetic intoxication, pregnancy, protein poisoning, the toxæmia of fevers, migraine, uræmia, &c. Also by this means suitable preventive and curative treatment might be indicated.

Literature of the Subject.

As to the clinical incidence of radiation toxæmia, of 160 cases noted by Miescher 60 per cent. showed no disturbance clinically; in the 40 per cent. which showed disturbance this was most marked when the radiation was on the epigastric area. Of 81 cases noted by Groedel and Lossen sickness was noted in every fourth case radiated on the head or neck, in every third case radiated on the thorax, and in every second abdominal case, their conclusion being that the "sickness" depends on the amount of glandular tissue radiated.

The literature on the different hypotheses and the clinical and experimental findings is already large.

The factor of gas poisoning has been suggested and worked at by Pfahler. Guthmann, and others. Rieder suggested the possibility of the induced high voltage of the patient's body during intensive X ray treatments. Edsall and Pemberton in 1907 put forward the view that the toxic products of nucleo-protein decomposition, which the kidneys were not able to excrete quickly, were the chief cause of the condition, which they regarded as an acute toxæmia. The white blood cell destruction may stimulate enzymes, especially autolytic ones. This aspect was reviewed by Richards in 1914–15. A degree of toxic nephritis has been suggested, causing a transitory uræmia, but, if present, this has not been of sufficient intensity experimentally to show definite histological changes. Proteoses can, however, depress the renal function for many hours to a quarter of the normal (Hall and Whipple).

Andersen and Kohlmann, as already noted, view the condition as similar to an acute uræmia; they find changes in the mineral content of the blood, in the calcium, sodium, and potassium content, the calcium being increased and potassium decreased at first, becoming normal again in 24 hours, the sodium being lessened for several days. They view roentgen sickness as vagus stimulation, causing altered blood mineral content, and they recommend calcium salts by mouth and intravenously for prophylaxis and in treatment of the established condition. Nürnberger found increased blood-sugar on the first and second days. Lange brought forward an acidosis hypothesis, which, as Sir Humphry Rolleston says in his recent masterly survey of the subject, has not received the attention it deserves. Observations on the point are few and contradictory. Denis, Aldrich, and Martin found acidosis in rabbits. Case found tests for acidosis negative. Golden found in patients and dogs no less alkali reserve, therefore no acidosis. Hussey found in rabbits increased alkali reserve 24 hours after. Lange recommended sodium bicarbonate treatment. The anaphylaxis view of Bergonié and others is apparently negatived by the fact that the reaction occurs as markedly after the first exposure as after later exposure. Also Hall and Whipple found in dogs rather an increased tolerance than otherwise with repeated exposures. Prendergrass and others, as a result of radium experiments on the brain, conclude that there is first a nuclear death, then the nerve cells are acted on by intracellular ferments, lecithin lipoids are broken up into neurin and cholin, and these when set free are autolytic causes of toxæmia. The chemical imitation of the effects of radiation by injection of cholin and enzytol (Werner) may here be mentioned. Autolytic changes in the intestinal epithelium have been specially noted by Hall and Whipple in their long series of experiments on dogs. The changes were very marked with massive fatal or sub-fatal doses, and were comparable with those found in acute hæmorrhagic pancreatitis or acute intestinal obstruction.

They regard X ray intoxication as similar to the intoxication after burns, due to toxic protein decomposition products. They found a latent period of 24 hours or longer, and a fourth-day maximum of toxic effect. They found no evidence of a true nephritis, and the chemical changes they noted were a 50–75 per cent. increase in the urinary nitrogen, increased purin bases, and phosphorus radicles. The non-protein nitrogen in the blood was two to three times the normal. On the whole, however, they found no very constant alteration in the blood as regards urea-nitrogen, total non-protein nitrogen, uric acid, creatinine, or sugar. But the chief difference from the normal they found was a deviation in the acid-base equilibrium, with increase in the hydrogen-ion concentration just after the treatment, and sometimes a slight lowering of the alkali reserve, and after 24 hours a diminished hydrogen-ion concentration and an increased alkali reserve. Whether this disturbance is comparable with the disturbance in fevers, &c., of the acid-base equilibrium remains for further research. Also as to its mechanism in irradiation it is not yet clear whether this change is due to alterations in the colloidal cell and serum equilibrium, as Hardy's experiments with acid and alkali globulin suggested, and as Colwell (quoted by Rolleston) has speculated. X and gamma radiation acting, so far as we understand, solely by the emission of negative beta-corpuscular radiation, might be expected to cause a transitory local and general increase in acid content. Thus would Lange's hypothesis of local and general acidosis find some support, as one aspect of the radiation effect.

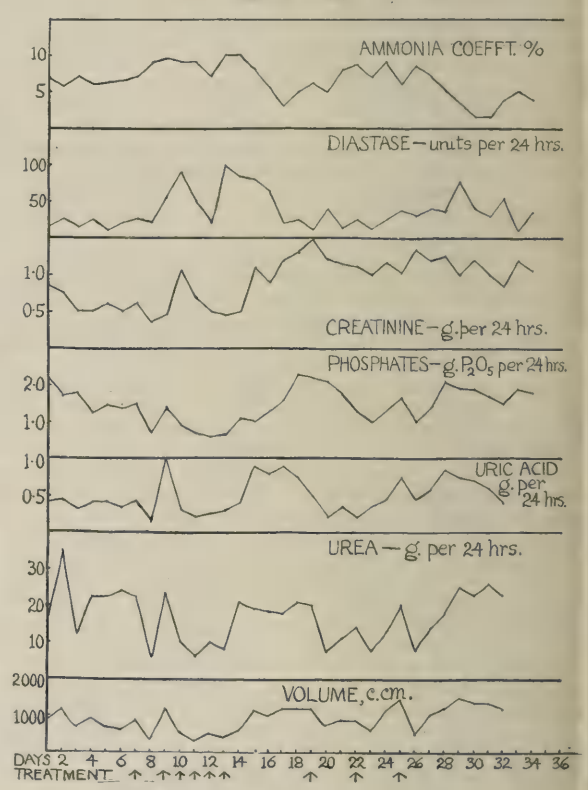
A more complete study of the problems involved than is here attempted would inter-relate the clinical and technical variations more fully with the laboratory findings. Patients might be grouped as to the skin surface area radiation both in intensity and time, according to the depth or "volume dose," also to the site of radiation, such as glandular, splanchnic, or more indifferent areas, and again as to age, sex, &c.

The Present Investigation.

Owing to the enormous amount of labour involved in investigating even a single case, our numbers are too small to enter into discussion on such points of detail. The patients studied were from four clinical groups: (1) cases of leukæmia; (2) cases of exophthalmic goitre; (3) prophylactic post-operative radiation of breast cases; and (4) radiation of patients with malignant disease in various parts of the body. Cases in Group 1 were treated with radium to the enlarged spleen, with or without X radiation to the long bones or enlarged glands. The method of Ordway and Giffin was followed, with minor modifications, in using the radium. Cases in Group 2 were treated with X radiation to the thyroid (and thymus in some instances). A shorter X ray wave-length was used in a few of Group 3 cases and in all of Group 4 cases; thus a wide range of X and gamma wave-lengths was used.

In this preliminary investigation it was decided to confine our attention mainly to the urine, although some blood observations were made. The effect of

CHART 1.

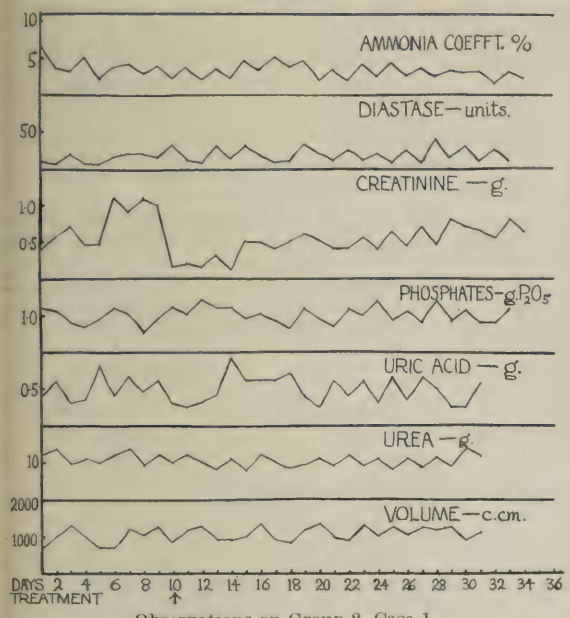


Observations on Group 1, Case 1.

radium and X rays on human subjects is a very difficult matter to investigate. Since it is impossible to observe the effects of radiation on normal human subjects, the investigator is forced to work with diseased individuals; hence he will have three factors complicating his results—the disease in question, the effect of treatment on the disease, and, finally, the effect of the rays on the patient's metabolism.

All the patients of this series were in bed, and were maintained on a constant diet. We were not

CHART 2.



Observations on Group 2, Case 1.

able to keep the diet purin-free, as in the experiment of Knudson and Erdos. The urine was collected in 24-hour specimens, which were completely analysed. All cases were examined for at least a week before treatment commenced, in order to fix the normal levels of their urinary constituents. Specimens were analysed so long as the patients remained in hospital. The following observations were made on each specimen: volume, urea, uric acid, ammonia, acidity, total nitrogen, ammonia coefficient, phosphates, chlorides, creatinine, and diastase. As some of the investigations extended over five months it is impossible to publish tables showing all results. Three charts are given (Charts 1, 2, and 3), showing those constituents in which most variation was found, and a general statement based on the tables is also given.

Results.

After a careful review of the results it was thought best to classify the observations according to the site of radiation. These fall under four headings: (1) abdominal irradiation; (2) cervical irradiation; (3) thoracic irradiation; and (4) irradiation of any other part of the body.

1. *Results of Abdominal Irradiation.*—In this group five cases were investigated.

CASE 1.—Male, aged 62, admitted suffering from lymphatic leukæmia. He was treated with radium applied to the spleen. The urinary observations were carried on throughout the treatment, a period of four months.

CASE 2.—Male, aged 31, admitted with a carcinoma of the testicle; this was removed, but complete removal of aortic glands was found to be impossible. Intensive X rays were applied to the abdominal gland area.

CASE 3.—Male, aged 41, suffering from spleno-medullary leukæmia. Radium was applied to the spleen and X rays to the long bones.

CASE 4.—Female, aged 46, with carcinoma of the sigmoid colon; the growth was removed after a colostomy had been done; recurrence in and near the colostomy. Intensive X ray treatment was given.

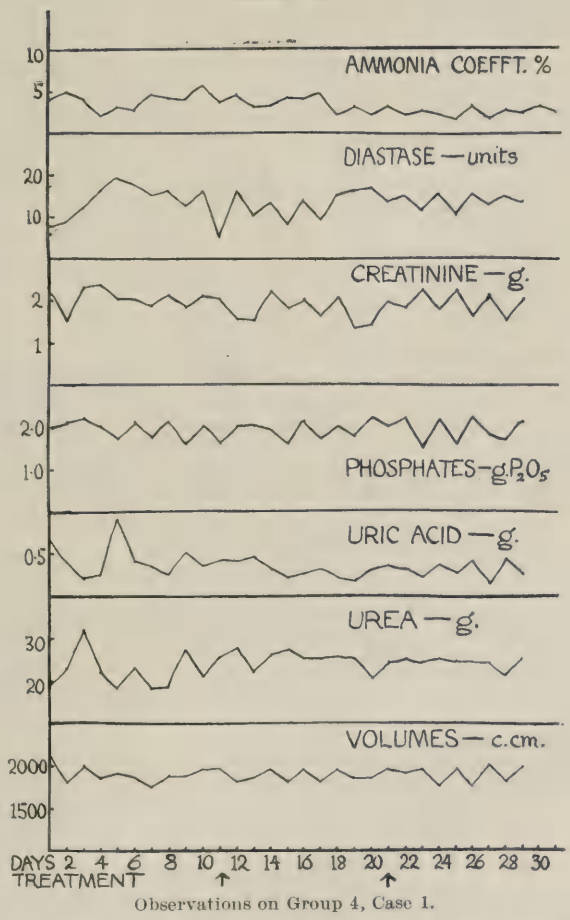
CASE 5.—Male, aged 30, with spleno-medullary leukæmia, treated with radium to the spleen.

In all this series of cases, there was a profound effect on the urine. The results are shown in the following summary.

Volume: Sudden fall to half of normal, recovery in two days.
Urea: Sudden fall to one-eighth of normal, recovery in two days.
Uric acid: Sudden fall to half of normal, rise in three days above normal, recovery in five days.
Ammonia: Sudden fall to 0·7 of normal, recovery in three days.
Acidity: Sudden fall to 0·7 of normal, recovery in three days.
Ammonia coefficient: Rise for three days, fall to normal in six days.
Creatinine: Slight fall.
Phosphates: Slight fall, followed by rise, normal in four days.
Chlorides: Slight rise, normal in six days.
Diastase: Sudden rise, normal in two days.
Total nitrogen: Slight fall, normal in two days.

These results were observed in all the cases investigated. Since it is impossible to reproduce all the

CHART 3.



Observations on Group 4, Case 1.

tables, the chart of Case 1 is published. This shows the variation in volume, ammonia coefficient, uric acid, urea, diastase, and phosphates.

2. *Thyroid or Cervical Irradiation.*—In this group 2 cases were examined, both being cases of exophthalmic goitre.

CASE 1.—Female, aged 45; both sides of neck irradiated (X rays).

CASE 2.—Female, aged 30; both sides of neck irradiated (X rays).

The results of urinary analysis on these cases are quite different from those in Group 1. There was no marked change in any of the urinary constituents

excepting creatinine. This body practically disappears from the urine during the period of irradiation, falling from 1·0 g. to 0·16 g. per 24 hours in Case 1, and from 1·2 g. to 0·09 g. in Case 2. The creatinine did not reach its normal level for four days. The exact explanation of this is very difficult. It has been held that the parathyroids are responsible for some part of creatinine metabolism, probably the conversion of guanidine into creatinine. The above effect could be explained on these lines, assuming that the radiation temporarily paralysed the action of the parathyroid glands.

3. *Thoracic Irradiation.*—Three cases were investigated (including two carcinoma mammæ), but no change was found.

4. *Irradiation of any other Part of the Body.*—A series of cases, with growths of the face and extremities, was investigated, but no change could be found.

Investigation of Blood.

Blood was collected from patients in each case of the above groups before and at varying times after irradiation. The results are shown in Table I. It can be seen that the results are mainly in accordance with the findings on rat's blood—namely, a marked fall in the blood-urea content, with very little change in any of the other constituents.

TABLE I.

Group.	Case.	Particulars of case.	Non-protein nitrogen.	Urea.	Uric acid.	Amino-acid nitrogen.	Sugar.	Chlorides.	Creatinine.

Investigation of Fæces.

The fæces were analysed for fat content. The results are given in Table II. There is a rise in fæcal fat content in cases of abdominal irradiation, but no effect could be discovered when other parts of the body were subjected to treatment.

TABLE II.—*Fæces Collected on the Second Day After Irradiation.*

Conclusions.

(1) Exactly similar results were found in patients treated with X or with gamma rays.

(2) The changes in metabolism produced in the patients were found to vary with the site radiated. The changes are summarised as follows:—

(*a*) Irradiation of the head, thorax, and limbs produced no change in the metabolism of the cases examined by us.

(*b*) Radiation of the abdomen and spleen produced definite urinary and blood changes—namely, there was a sudden fall in the 24-hourly amounts of the following urinary constituents: urea, uric acid, ammonia, and titratable acidity, creatinine, total nitrogen, and phosphates. The volume of the urine was also greatly decreased. After some three days the excretion of these substances rose to about the normal figure. In the case of uric acid, and of phosphates, the 24-hourly amounts continued to increase after the original level had been reached, but returned to normal again in about five days. The chloride content and diastase showed an immediate increase, returning to normal in about three to six days. The ammonia coefficient showed an increase for about three days, falling to normal in six days. Blood analysis showed a marked decrease in the urea content, with very little change in any other of the blood constituents. These results were obtained in every case of this group investigated. Examination of the fæces showed an immediate increase in the fæcal fat content. This increase is almost solely in the neutral fat fraction.

From these results it would appear that the effects of radiating the abdomen can be explained by a temporary inhibition of the functions of the principal abdominal glands, such as the liver, pancreas, and kidneys. It can be seen that our figures give no support to the acute uræmic theory of Andersen and Kohlmann. We could obtain no evidence of nitrogen retention such as would be expected if uræmia had been induced. These workers based their conclusions on analysis of the mineral content of the blood, a line of work not touched by us, yet most workers will agree that there is always evidence of nitrogen retention in cases of uræmia. The rise in the ammonia coefficient following radiation is in agreement with the acidosis theory of Lange. The increase in the fæcal fat content also supports the work of Whipple and Hall, who showed that radiation of dogs produced marked alimentary symptoms, even verging on to pancreatitis if the dose were large enough. The fall in urea content of the blood is very difficult to explain, but it would appear to us that it might be brought about by a temporary inhibition of the metabolic functions of the liver.

(*c*) Radiation of the cervical region produced no change in the metabolism as evinced by a study of the blood and urine except in one respect. There was an immediate fall in the excretion of urinary creatinine. On the day after exposure this body almost disappeared from the urine, and recovery did not take place until about the fourth day. Practically no alteration in the blood creatinine content was found. This curious effect might be explained by assuming that the parathyroids had been temporarily paralysed, and could not play their normal part in the metabolism of creatinine, which is supposed to be the conversion of guanidine into creatinine.

(3) Three cases of very well marked X ray sickness were examined, but no change in their metabolism following exposure to rays could be detected. The sickness in these cases was apparently psychical.

(4) A considerable number of cases have been treated prophylactically with calcium chloride, &c., before radiation, and a few with sodium bicarbonate; all such cases show less reaction. In the light of the results set forth in this paper, prophylactic measures are being thoroughly investigated.

We have to express appreciation of the interest and kindness of members of the hospital staff, more especially Dr. R. A. Young, Dr. C. E. Lakin, Mr. W. Sampson Handley, and Mr. G. Gordon-Taylor. The amount of work involved in making the analyses detailed in this paper was very great, and we have to thank the members of the staff of the biochemical department who participated therein. This work was made possible through the generosity of Sir William Veno.

EXPERIMENTAL AND THERAPEUTIC ALTERATIONS OF HUMAN TISSUE ALKALINITY.*

By J. B. S. HALDANE, M.A.,
DUNN READER IN BIOCHEMISTRY, CAMBRIDGE UNIVERSITY.

THE hydrogen-ion concentration in any tissue depends on the ratio of free carbonic acid to bicarbonate in it. For

$$\overset{+}{H} + H\bar{C}O_3 \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2.$$

And since the water concentration varies little, we have approximately

$$[\overset{+}{H}] \times [H\bar{C}O_3] = k[CO_2]$$

$$\therefore cH = [\overset{+}{H}] = \frac{k[CO_2]}{[H\bar{C}O_3]}.$$

The hydrogen-ion concentration of the tissues may be altered by varying the numerator of this fraction, the CO_2 pressure. This occurs in respiratory disease, and can be produced experimentally by CO_2 inhalation on voluntary overbreathing, but such measures can rarely be employed in therapeutics. It is much easier to alter the bicarbonate concentration. This can be increased by the ingestion either of sodium bicarbonate or the sodium salt of an organic acid, such as acetic or citric, which is rapidly oxidised to bicarbonate. It can be diminished by taking chlorides or certain other salts of ammonium or calcium. Ammonium chloride is absorbed from the gut and converted in the liver and perhaps elsewhere into urea, the hydrochloric acid neutralising bicarbonate.

$$2\,NH_4Cl + 2\,NaHCO_3 = CON_2H_4 + 2\,NaCl + H_2O + 3CO.$$

Calcium chloride reacts in the gut with the alkaline digestive juices, forming calcium carbonate which is excreted per anum, the sodium chloride formed being reabsorbed.

$$CaCl_2 + 2\,NaHCO_3 = CaCO_3 + 2\,NaCl + H_2O + CO_2$$

In each case the final result is the same as if hydrochloric acid had been taken. The urea formed from ammonium chloride is unimportant, but about 10 per cent. of the calcium of calcium chloride is absorbed and causes unpleasant symptoms.

Dosage of Inorganic Salts.

To get a marked effect with inorganic salts, as with alkaloids, we must take an appreciable fraction of the lethal dose. Appropriate doses for adults are 45 g. $NaHCO_3$, 70 g. $NaC_2H_3O_2{\cdot}3H_2O$, 20 g. NH_4Cl, 45 g. $CaCl_2{\cdot}6H_2O$. Sodium acetate is much less nauseating and purgative than bicarbonate, and causes no eructation, but it is uncertain how completely large doses are oxidised. Ammonium chloride may cause vomiting in strengths over 2 per cent., whilst calcium chloride produces violent diarrhœa. The results which I am putting forward are mainly those obtained with the above doses of these substances by various colleagues and myself in human experiments at Oxford and Cambridge in the last five years.

Sodium bicarbonate is very rapidly excreted, but it is possible to increase the bicarbonate or "alkali reserve" of the blood by 20 per cent. by its ingestion. The alveolar CO_2 pressure rises by much the same amount owing to a slowing down of the breathing, so the reaction of the arterial blood is little altered, though the liver doubtless becomes very alkaline. The urine may contain 3 per cent. of sodium bicarbonate and be free from ammonia. Similar effects are obtained with the acetate.

Ammonium chloride may reduce the alkali reserve and alveolar CO_2 pressure to less than half the normal values. The acid excretion in the urine may rise to four times, the ammonia excretion to six times the normal value. But except for hyperpnœa, which is only distressing during exercise, no discomfort is felt. Clinically, acidosis is generally associated with acetone body formation or uræmia. When, however, the bicarbonate of the blood is merely replaced by chloride we have an uncomplicated acidosis, which has no serious effects until at least two-thirds of the lethal dose has been taken. After such an acidosis the alkali reserve does not return to normal for four or five days, so the effect of doses is cumulative.

Alkalosis, whether due to overbreathing or alkali ingestion, causes an upset of carbohydrate metabolism like that of diabetes. Aceto-acetic and β-oxybutyric acids appear in the urine. The respiratory quotient falls, sometimes to 0·70 and lower, showing that no carbohydrate is being oxidised. The fasting blood-sugar rises only slightly, but polarimetric examination by the method of Winter and Smith shows that, as in diabetes, the normal sugar has been replaced by a highly dextro-rotatory substance. My normal glucose tolerance is more than 200 g., but a dose of 100 g. taken five hours after 60 g. of bicarbonate gave a rise of blood-sugar to 0·19 per cent. with a very slow fall, and glycosuria, without abolishing the acetonuria.

Limitations of Alkali Treatment.

Such results emphasise two points. First, acetonuria should not be treated with alkalies unless there is reason to suspect serious acidosis. Secondly, although alkali treatment saves life in diabetic coma, there is no reason for pushing it to the point of re-establishing the normal alkali reserve. Adlersberg has gone further, and deliberately induced acidosis in mild cases of diabetes by doses of 18 g. per day of $H_2NH_4PO_4$, which is less nauseating than NH_4Cl, but acts as a purgative. He was able to halve the urinary acetone excretion and in some cases the glucose excretion also. However, he does not report many cases, and his results may be due in part to the increase of phosphates in the blood. But the probability remains that glucose is best oxidised somewhat on the acid side of the normal reaction.

When, however, the acidosis is pressed too far a different type of disturbance of carbohydrate metabolism arises (in me at least). There is no acetonuria and the respiratory quotient is normal or high—i.e. carbohydrates are easily oxidised; moreover, the rotatory power and fasting level of the blood-sugar is normal. But it rises rapidly after meals, and 100 g. of glucose produce a rise to 0·19 per cent. and glycosuria. There is a failure to store glucose, but not to oxidise it, and the condition is therefore not analogous to diabetes, as believed by authors who produced it in animals. This condition, which may be due to liver damage, appears late in the course of the acidosis and outlasts it. In severe diabetes with acidosis it is

* A summary of remarks made at a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on Feb. 12th, 1924.

presumably superimposed on the failure of pancreatic function, and an improved glucose tolerance as the result of treatment cannot be taken to indicate a better formation of insulin by the pancreas, or an increased power of oxidising glucose.

Ammonium chloride acidosis has a large effect on inorganic metabolism. We have observed the following urinary excretions per day expressed in percentages of the normal values: Na 250 per cent., K 520 per cent., Ca 330 per cent., P 180 per cent. The first three elements serve to neutralise the acid, the latter to "buffer" the urine. The calcium content of the serum rises by about 10 per cent. Calcium chloride may cause a rise of 25 per cent., the effect of calcium absorption being superimposed on that of acidosis. American observers who were unable to raise their serum calcium had contented themselves with one-tenth of the dosage which we employed. Sodium bicarbonate lowers the serum calcium 10–20 per cent. Ammonium and calcium chlorides are very powerful diuretics. After 65 g. of NH_4Cl in three days my weight falls about 7 lb. and the hæmoglobin of the blood rises by 20 per cent., even although I drink freely. This and the salt excretion are probably due to the fact that the colloids of the body, being brought nearer their iso-electric points, retain less water and salts. Blum and his pupils have found calcium chloride a valuable dehydrating agent in certain types of dropsy and œdema, and it seems likely that ammonium chloride might have a similar effect without producing diarrhœa and malaise. It also appears that the therapy of acidosis should include a liberal supply of potassium and phosphates in cases where the kidneys have been in a position to excrete them.

Therapeutic Use of Ammonium Chloride.

The only serious therapeutic use of ammonium chloride so far has been in the treatment of tetany, where Freudenberg and György have used it with striking effect. In infantile tetany the symptoms vanish in a few hours, and satisfactory results have also been obtained in gastric and post-operative cases. In a series of infants treated with ½ g. per kilo per day of ammonium chloride the serum calcium rose from a mean value of 6·6 mg. per cent. to 8·9, the phosphorus falling from 4·9 to 2·9. In one American case ammonium chloride was given intravenously with success, but in view of its possible convulsant effects rectal administration would appear preferable when it cannot be given by the mouth.

The rationale of this treatment is the fact that tetany is always produced by forced breathing and sometimes by alkali ingestion. And although many cases may be due to guanidine poisoning, it is probable that even so a given amount of guanidine may be less effective when the calcium of the plasma is increased and its alkalinity diminished.

Many other facts of interest have arisen in the course of the investigations here summarised, notably with regard to oxygen consumption and the metabolism of organic phosphorus compounds, but their application to practical medicine is not yet clear. Moreover, a few of the results here given have only been obtained on a single individual, while their causation is often obscure. They seem, however, to point to therapeutic applications in many fields of medicine, and to testify to the value of experiments on men.

HYDROPHOBIA IN EGYPT.

BY ROBERT V. DOLBEY, M.S. LOND., F.R.C.S. ENG.,

DIRECTOR OF THE SURGICAL UNIT, SURGEON TO THE KASR-EL-AINY HOSPITAL, CAIRO;

AND

DR. ABDULLAH EL KATIB,

MEDICAL RESIDENT, KASR-EL-AINY HOSPITAL.

THERE can be few medical schools in the world with such opportunities for the study of this disease as Kasr-el-Ainy in Cairo. Rabies is an endemic disease among the dogs, the jackals, and the desert wolves in Egypt. To this hospital are admitted all cases of animal bites of Egypt by order of the Ministry of the Interior. In all, the police bring some 2000 cases of animal bite a year; while probably just as many escape the police regulations. We have a medical school, a pathological institute, and an anti-rabic institute, modelled on the lines of the Pasteur Institute, all adjacent. Students enjoy the fullest opportunities of seeing the preparation of dried cords, and inoculation experiments in rabbits, as well as the clinical evidences of hydrophobia developing in our wards.

The clinical aspect of this disease is of the greatest value; for we can observe the earliest development of symptoms as well as the fully developed cases that come to the reception room. The number of cases of hydrophobia is about 15 a year; about half of which develop in hospital and the other half are admitted with symptoms fully developed. The anti-vivisectionists, whose excess of sympathy for the animal kingdom prompts them to oppose any scientific investigation based on animal experimentation, deny the existence of this disease either in animals or in human beings. In animals it is said to be one of the manifestations of sunstroke, and in human beings hysteria. Of all sweeping assertions none has less foundation than this. If one observes the children who develop hydrophobia in hospital one will be convinced that there is no question of suggestion with them. Our English sisters, who are the most experienced of us all in the recognition of this disease, fully bear out this opinion. The initial insomnia, the mental state, the rise in temperature, the terror that is so characteristic, and the gradual development through recognised stages to the fatal ending, should be sufficient to convince any sceptic. Again, in Egypt we have to deal with a simple, lowly-organised fellaheen population that is remarkably free from hysteria or functional disease in any of its manifestations.

Types of Animal Bites.

The worst animal bite is that of the camel. The lateral grinding movement of its jaw produces a compound fracture of the long bones; fractures even of the femur and tibia can be caused by camel bites alone, but the incidence of rabies in these animals is low. The rutting season in camels is associated with the development of foam around the mouth of the male; but this is essentially different from the dribbling saliva of the paralytic stage of the rabid camel. The next most serious bite is that of the pig. Though not associated with compound fracture, it is yet the most lacerating of all wounds; a pig can tear the hamstring muscles out of the human thigh. But the incidence of rabies also is low in the pig. From the point of view of the development of hydrophobia the bites of desert wolves and jackals (most jackals are incorrectly called wolves in Egypt) are the most dangerous. A jackal bites the throat and face particularly; and, in fact, the bite of this animal, when it cannot be killed and examined, must be looked upon as potentially liable to produce hydrophobia. The tendency for rabid animals to change their habits and character is responsible for

many of the attacks on human beings. A normal jackal does not frequent cultivated land in the day-time, and is usually so shy as never to attack human beings. By day he is in the rocks and holes of the desert hills. The mere fact of a jackal lying up in a sheltered spot in the fields in the day-time or attacking human beings is strongly suggestive of rabies. The first stage of rabies in our dogs is change of character, shown especially by the habit of standing in the hot sun in an aimless way. The second stage is that of violence, the biting of wood or any object, animate or inanimate, without reason. This is also associated with a tendency to hide behind a bush or in a fence. The third stage is the paralytic one, in which the dog is not really dangerous unless petted or caught. The jaw drops, the legs drag behind him, and saliva dribbles from his mouth, owing to the inability to close the jaws. Of all dogs the discarded hareem pet is most liable to infection. He is taken to the house to amuse the children when a puppy, then driven out when fully grown and forced to wander with no fixed duty or inclination at night-time, when he meets the rabid jackal and goes to see why the latter's movements are so peculiar. Sheep-dogs and house-dogs are not so often affected.

The position and character of the bite are of great importance. Deep lacerating wounds from the canine teeth of wolves or jackals are most dangerous, especially on uncovered areas of the body.

Our experience in Egypt differs from that of workers at Kasauli in India, or Buda-Pesth, or at the Pasteur Institute. The incidence of hydrophobia in our people admittedly bitten by rabid dogs is not so high, nor is the latent period of the development of the disease so prolonged. There is a curious belief in Egypt that if symptoms do not develop before the fortieth day after the bite, they will not develop at all. In our experience this is correct; for of all the cases of hydrophobia in Kasr-el-Ainy in the last four years not one developed it after the fortieth day. The average day was the nineteenth, whether the case was treated by injections of emulsion alone, or of emulsion and serum, or untreated in any way. In fact, the majority of the cases developing in hospital do so just before they are about to be discharged after the twenty-first daily injection. Our experience as to the development of hydrophobia is that 50 per cent. of untreated cases of admittedly rabid wolf-bites of the face develop symptoms of the disease; that 10 per cent. of these cases develop symptoms even if treated; but that of bites in general from all sources (and, of course, dog-bites are the most common) less than 1 per cent. develop the disease. The difficulty that confronts the compilation of all statistics of this disease is that of definitely knowing if the biting animal is rabid or not. The latter either escapes entirely or is shot; in the latter case his brain is usually destroyed and so decomposed by the time it reaches the Anti-Rabic Institute that inoculation experiments with rabbits are out of the question.

Diagnosis.

The diagnosis of hydrophobia can be made with almost certain accuracy from the clinical symptoms. The only absolute proof, of course, is the inoculation of filtered human saliva into the brain of a rabbit. Even then care has to be taken that a simple infective meningitis is not mistaken for rabies in the rabbit. The disease is a fascinating study. It is surrounded by an atmosphere of fear of infection among students, doctors, and attendants that is not in the least justified. Not one case of hydrophobia has ever developed in Kasr-el-Ainy among the attendants. One case, however, did develop in Egypt during the war, in an English sister who nursed a soldier suffering from what appeared, at first, to be epileptic fits. She died; but another sister who was equally exposed to infection did not develop the disease. Both were treated by emulsion and by serum.

In our hospital cases the first symptom is a rise in temperature and, for that reason, we watch the fever charts of our dog-bite cases very carefully even when the wound is healed. The next symptom, a very regular one, is insomnia; the patient sits up in bed all night and is disturbed mentally. These cases are nearly always diagnosed by the night sisters. Not, as a rule, until three days have elapsed from the development of these premonitory symptoms does the typical and so-called pharyngeal spasm develop. It is not a pharyngeal spasm at all; it is a spasm of the diaphragm. This symptom can be most aptly compared with the long shuddering inspiratory clonic spasm of the diaphragm that takes place when a child is immersed in cold water. All the accessory muscles of respiration in the neck stand out like cords, and the thorax is raised and fixed. But before this spasm, which is taken, quite rightly, as pathognomonic of the disease, develops, there is a curious and characteristic mental state of uniform and unmistakable terror. (Four other diseases in Egypt are also associated with fear; they are cholera, plague, tetanus, and angina pectoris.) A fear of some impending evil is written in the patient's eyes and in the facial expression; there is also an extreme anxiety to please, but at the same time a deterioration in intelligence. The wound begins to be painful, although it may have healed and there is no sign of inflammation. The patient is at first most amenable to suggestion or to any order, but it has to be repeated more than once. He is so ready to oblige that, if told to lie down in bed, he springs into the bed and betrays an excessive desire to be helpful and obedient. The voice is staccato in character, and we attach great importance to this symptom. This preliminary mental state is very characteristic. Later, usually within 24 hours, when the diaphragmatic spasm has developed, the diagnosis is beyond question; but then the violent terminal stage is near and the patient may soon be difficult to control. Before the stage of spasm it is possible to elicit the spasm of facial muscles and an inspiratory spasm by blowing upon the face. This is diagnostic at this stage and, later, also when the true diaphragmatic spasm has developed. It is a much more merciful, less painful and less distressing method of eliciting this symptom than to ask the patient to drink. When spasm has developed the swallowing of semi-solids is sometimes—and often in children—possible when the swallowing of liquid provokes spasm. Again, the sight of water alone provokes spasm; it is sometimes possible for the patient to drink from a rubber tube attached to a feeding cup in which no water is visible. Usually water in an open vessel induces immediate spasm.

In children, however, the symptoms are sometimes not classical, and these little patients may die without developing any spasm at all, and may drink in comfort up to the end. From the development of spasm the disease in adults lasts, as a rule, 48 hours; and death is due to a generalised neuritis and paralysis of the higher centres. But in children the disease may last five to seven days, and death may be sometimes accelerated by fluid starvation. Such is the disinclination, owing to the fear of infection on the part of some attendants, to apply the ordinary rules of nursing that one feels the want of fluid is partly responsible. In some of our cases, however, the patients have been given saline and nutrient enemata by the sisters to the end. Stomach-tube treatment is only possible under an anæsthetic, and is possibly quite ineffectual, inasmuch as the food appears to pass entirely indigested. The eyes become early inflamed, and muco-pus gathers in the internal canthus. Around the edges of the mouth dried mucus collects. The patient spits all over the floor.

The terminal violent stage is characteristic. The terror is most pronounced and suspicion is most marked. Often if one approaches alone it is possible to give a hypodermic injection; but if a crowd of attendants are present their fear and alarm is so easily conveyed to the patient that no efforts are of any avail. Until the final eight hours, when, as a rule, paralysis of the lower limbs develop and the patient drags himself about the floor, the violence is chiefly directed to climbing the walls of the strong room or

attempting to reach the embrasure of the window. All clothing is torn off, and the patients always die naked unless treated with hyoscine. The spectacle is a pitiable one. These patients, though inclined to crouch in a corner, are yet afraid of darkness. In their delirium they recapitulate the incidents of the dog or wolf attack, and they have delusions of vision and of hearing. They are always quieter in the light, either daylight or artificial. Children retain the remembrance of friendly faces almost until the end, and can be nursed and comforted by their accustomed nurses or sisters when the sight of a doctor rouses immediate terror. Usually, when the spasm has developed, symptoms of neuritis of the legs develop also, and knee-jerks and ankle-jerks and plantar reflexes are lost; in some cases the latter are exaggerated until the end. There is no change in the pupil reflex. The noises which are so often referred to as "dog-barking" or "wolf howls" have no foundation in fact whatsoever. They exist only in the imagination of observers. There is inspiratory phonation during spasm, and constant chattering during the violent stage. Later on, phonation is discordant and articulation is lost; but never can one observe any semblance to the howl of a wolf. Nor do patients ever attack or try to bite attendants; they only resist treatment. This disease, however, is clothed with so much exaggeration and fear of infection that any story is possible to a lively imagination.

Treatment.

Our treatment of the bite is by the cautery or excision or by caustics. Then, until the animal is definitely proved to be non-rabid, by emulsions of dried cords of rabbits daily for 21 injections. If the bite is a severely lacerated one or a definite wolf-bite, or situated upon the face, the treatment given is by serum as well as by glycerine emulsion.

Our treatment of the symptoms is by hyoscine and morphia; then, when violence is controlled, the treatment that we adopt for the disease itself is the intravenous injection of novarsenobenzol or tartar emetic. This is largely empirical, on the presumption that we may have to deal with a filter-passing virus of the nature of that causing horse-sickness. But we have had no successful results to publish—unless it be one doubtful case that recovered, in whom the disease may have been aborted by an injection of 606. He exhibited the characteristic mental state, and spasm of the facial muscles could be elicited by blowing upon the face, but he had not developed the true diaphragmatic spasm. Steps are being taken to undertake inoculation experiments in rabbits with filtered saliva in all our doubtful cases.

The treatment of the disease, however, must be commenced at once. As swallowing is usually impossible and rectal treatment is not tolerated, recourse must be had to hypodermic injection. In some cases of children, without spasm, sulphonal in 3 gr. doses is effectual in controlling violence, but in adults hyoscine is the drug and the only drug. Morphia alone is useless; but when combined with hyoscine in doses of 1/50 gr. the violence is controlled and the patient can be nursed in a bed.

We have had no cases among Egyptians of hysteria simulating this disease or of the mimicry of symptoms in order to obtain sympathy or to base a claim for compensation; but we hear of one European who developed hysterical spasm of the pharyngeal muscles on his way down from Khartoum to Cairo for treatment. Rabies, by the way, is very rare indeed among the dogs or jackals in the Soudan.

Our pathological investigations into this disease are disappointing. Even in undoubted and fatal clinical cases of hydrophobia we only find Negri bodies in 20 per cent., either in the blood or in the region of the hippocampus major of the brain. The mortality is 100 per cent. as far as we know. But until we begin to inoculate rabbits as a routine method with filtered saliva we shall never be sure that some of our recovered cases with mental symptoms and signs of a peripheral neuritis are not, in fact, cases of cure or cases of hydrophobia modified by treatment.

We are indebted to Mr. A. E. Branch, Director-General of the Veterinary Service, for the following statement and figures of rabies prevention in Egypt:—

Eighty-one cases of rabies were reported during the year 1922, against 120 cases in the previous year.

The total number of dogs and cats destroyed during the year was 103,000—distributed as follows: Provinces, 74,416; Cairo, 13,543; Alexandria, 5966; Dogs' Home, Boulac, 9075. The Cairo police seized and sent to the Dogs' Home, Boulac, 10,988 dogs, of which number 9075 were destroyed.

The total number of animals placed under observation was 455, classified as follows: Dogs 400, cats 27, monkeys 20, horses 2, camels 1, donkeys 3, foxes 1, weasels 1.

MALARIA THERAPY IN GENERAL PARALYSIS OF THE INSANE.

BY A. R. GRANT, M.B., CH.B. ABERD.,
DEPUTY MEDICAL SUPERINTENDENT, COUNTY MENTAL HOSPITAL, WHITTINGHAM, PRESTON, LANCS;

AND

J. D. SILVERSTON, M.B., B.S. DURH.,
SENIOR ASSISTANT MEDICAL OFFICER AT THE HOSPITAL.

DURING the past few months several articles on the treatment of general paralysis of the insane by inoculation with malaria have appeared in the medical press of this country, but, so far as we have seen, no detailed report on the reactions of the blood and cerebro-spinal fluid after treatment has been published. In this preliminary report we propose to deal with our observations on the blood and cerebro-spinal fluids (C.-S.F.) of 40 cases treated at the County of Lancaster Mental Hospital, Whittingham. For one reason or another it was not possible to apply all the tests in some of the cases, but comparisons have been drawn wherever possible.

Of the 40 cases reported on, 16 had a course of preparations of salvarsan after the malaria had been arrested by the administration of quinine. In these cases the blood and C.-S.F. were not examined until at least one month after the administration of the last dose of salvarsan. In some cases several examinations of the blood and fluid were made to investigate the possibility of progressive changes in the findings. In all, 49 C.-S.F. examinations and 46 blood examinations were made after treatment. Of the 40 cases we review, in 40 per cent. the fluid was examined during the first month after treatment had been stopped, in 10 per cent. during the second month, in 30 per cent. between the third and sixth month, and, finally, in 20 per cent. between the sixth and thirteenth month. The accompanying table contains a synopsis of the readings of the C.-S.F. and blood reactions both before and after treatment.

1. *Colour.*

Xanthochromia occurred in one of our series (Case 33). Lumbar puncture two days following the disappearance of the *Plasmodium vivax* from the circulating blood revealed a yellow fluid, intensely stained, even following prolonged centrifugalisation at a high velocity. Spontaneous coagulation or a marked increase in protein was absent, whilst the chemical tests for bile gave consistently negative results. A microscopic examination of the centrifuged deposit revealed broken-down and effete red cells and granular debris. The colour persisted for a short time only, as a series of punctures at intervals of a few days manifested a gradual diminution in its intensity with final disappearance of all colouring matter at the end of 14 days.

2. *Cytology.*

A decrease in cells was an early change noted in 91·5 per cent. of 37 fluids examined. In this series they varied in number from 1·6 to 61 cells per c.mm. and were uniformly made up of small and large

lymphocytes, the large cell predominating. The decrease in the number of cells per c.mm. worked out as follows: between 0 and 5 cells per c.mm., 24·3 per cent.; between 5 and 10, 32·4 per cent.; 10 and over, 35·1 per cent. An actual increase took place in 8·2 per cent.

3. *Protein.*

A lowered protein content, as estimated by the ring test of Ross-Jones and the reaction of Pandy, was another early feature in the 49 per cent. of cases in which this phenomenon occurred. No change was observed in a little less than 45 per cent. of the series.

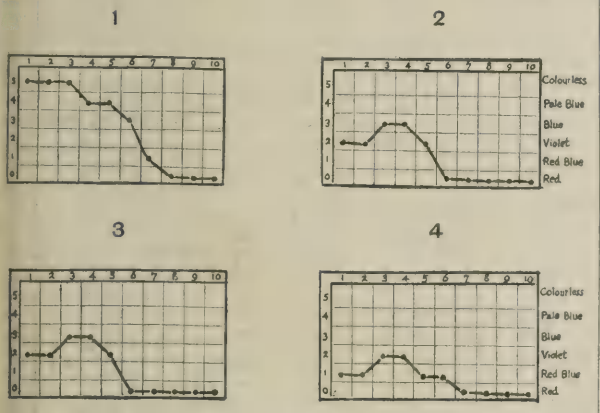
4. *Cellular Decrease with Lowered Protein Content.*

This combined change was seen in 64·8 per cent. of all treated cases. Comparisons were not made in those instances where red blood corpuscles were demonstrated by the microscope.

5. *The Colloidal Gold Reaction of Lange.*

The gold solution was prepared according to the method of Miller, Brush, Hammers, and Felton.[1] Each fresh supply of the reagent was tested before use with known normal and known general paralytic fluids, and the tests were carried out in the usual manner. In all cases the lumbar fluids were examined within an hour of their withdrawal. The readings were made in daylight and charted after the tubes had been allowed to stand at room temperature for 12 hours.

In expressing the results, the numeral 5 is used to indicate complete decolorisation due to complete



Case 21.—1. Curve before treatment, Nov. 2nd, 1922. The parasites disappeared May 2nd, 1923. 2. Curve on Sept. 7th. 3. Curve on Oct. 15th. 4. Curve on Dec. 14th.

precipitation of the colloidal gold, whereas the numbers 4, 3, 2, and 1 indicate the colours of pale blue, blue, violet, and red-blue respectively. No change in colour is represented by 0. The "paretic" curve shows complete decolorisation in the first few tubes (three or more), with lesser colour changes in the remainder, giving a reading such as 5555543210. Incomplete precipitation, but with general conformation of the curve, represented by a reading as 4444321000, would still be regarded as fairly typical. The "mid-zone" or "luetic" curve shows no change in the first one or two tubes, with the maximum colour reaction in the fourth or fifth tubes giving a reading as 0012211000.

The test was performed in the whole series of our cases and repeated at varying intervals in a few instances where a marked change in the reading first appeared. In this way we were able to observe and to follow the conversion of a typical "paretic" to a "luetic" curve. In none of our cases can we say that an absolute negative gold solution resulted from the malarial treatment. In 28 fluids, or 70 per cent. of the cases, the "paretic" curve remained unchanged, whilst in nine fluids, or 22·5 per cent., the "paretic" curve persisted, clouded, however, by a slight colour change. The first three or four tubes in these cases appeared as though the gold solution had been completely precipitated, except for a faint bright-pink coloration which we have expressed in the table as { 5555 / 4444432000.

"Luetic" curves were demonstrated in three fluids (Case Nos. 4, 21, and 39), or 7·5 per cent. of the series. Case 21 is very helpful in observing the changes through which the colours pass in the conversion of a "paretic" to a "luetic" curve. (See charts.)

6. *The Colloidal Gamboge Reaction.*[2]

The colloidal gamboge reaction was introduced as one of the routine tests of the C.-S.F. in our laboratory in the early months of 1922, when Riddel and Stewart found that by using a colloidal suspension of gamboge they were able to obtain "paretic" curves in 100 per cent. of the cases of general paralysis. Briefly the test is interpreted as follows: A negative reaction is shown by a total absence of precipitation in all six tubes and would be indicated in numerals with the reading 000000. Complete precipitation of the gamboge (indicated by the numeral 2) in the first three or more tubes is known as the "paretic" curve. This curve, seen in all our untreated cases of general paralysis, is represented by the reading 222220. Partial precipitation (indicated by the numeral 1) in the first three tubes, the "luetic" curve, is a fairly constant reading in cases of meningo-vascular syphilis. It reads 111000. In meningitis, complete precipitation occurs in the higher dilutions (tubes 4 and 5), tubes 1 and 2 usually remaining negative. The colloidal gamboge reaction in a recent case of pneumococcal meningitis (confirmed by autopsy) gave the reading 112220. The test was carried out with all the fluids of the series and the following observations were made. The "paretic" curve remained unchanged in 32 cases, or 80 per cent.; showed a slight change in seven cases, or 17·5 per cent.; whilst a "luetic" curve resulted in one case, or 2·5 per cent. of the series. A negative reaction was not obtained. In comparing the values of the two colloidal tests as an indication of changes in the C.-S.F. following the malaria treatment, it will be seen from these results that the percentage change in the gold solution (30 per cent.) was higher than the corresponding change (20 per cent.) in the gamboge reaction.

7. *The Wassermann Reaction of the Cerebro-spinal Fluid.*

Comparisons were possible in 29 fluids, as in this number of cases had records been kept both before and after treatment. In this series three became negative, six weakly positive or doubtful, whilst 20 remained unchanged. In the 11 cases where the W.R. was not obtained before treatment three negative findings occurred, making a sum total of six, or 15 per cent., negative serum reactions of the whole series.

8. *Wassermann Reaction of the Blood.*

The same difficulties as with the C.-S.F. allowed us to make comparisons in the readings of only 24 sera. A reduction in the intensity of the reaction was an early feature of the treated cases, and accounted for 17 of the 24 sera examined. Five remained unchanged, whilst two became negative. In all 40 cases, 23, or 57·5 per cent., were weakly positive or doubtful, and three, or 7·5 per cent., were negative. The W.R.'s of the C.-S.F. and blood were concurrently negative in two cases; three of the six negative W.R.'s of the C.-S.F., and all three of the negative blood W.R.'s, occurred in cases treated by salvarsan. Likewise to the two cases where the blood and C.-S.F. W.R.'s were concurrently negative salvarsan had been given.

Early changes observed were diminished protein content and a decrease in lymphocytosis of the fluid, and a reduction of the W.R. of the blood. A combina-

First line in each case represents the readings in the fluid and blood before treatment.
S = Case treated by malaria inoculation and salvarsan. S* = Xanthochromia. S† = Clear and colourless. E = Early case.
L = Case in late stages. f. + = faintly positive. N.D. = Not done. M = Male. F = Female.

tion of all three changes occurred in 16, or 40 per cent., of the whole series of cases. Of the 16 cases treated with salvarsan seven, or 43·7 per cent., of this series provided the same combination of changes. We were able to make further observations on the changes in the C.-S.F. in a series of 29 fluids where all the reactions had been carried out both before and after treatment:

(*a*) In six cases (vide cases Nos. 1, 3, 6, 8, 13, and 24), or 20·3 per cent., there were present in the fluid a lowered protein content, a cellular decrease, and a reduction in the fluid W.R.

(*b*) In two cases (vide cases Nos. 6, 13), or 6·7 per cent., there were seen in the fluid a lowered protein content, a cellular decrease, a reduction in the fluid W.R., and slight to marked changes in the gold-sol test. The gold-sol test was the last of the fluid reactions to show any change.

Salvarsan had been given in three of the six cases discussed in the subchapter (*a*) and to one of the cases mentioned in subchapter (*b*).

Summary.

In a series of 40 cases of general paralysis treated by inoculation with malaria, 16 of which received in addition a course of salvarsan, observations were made on the findings in the C.-S.F. and blood, and comparisons made where possible. As the times of the withdrawal of fluids following the fever treatment varied from one day to 13 months, we were able to observe whether immediate changes, if any, progressed or remained stationary.

No improvement in any of the cerebro-spinal fluid reactions occurred in one case—No. 15. It will be seen, however, that the W.R. of the blood was returned as doubtful, so that in reviewing the changes of the whole series of the liquor and serum reactions we obtained in *every* case some alteration either in the fluid or serum or in both following treatment.

The earliest signs of improvement were manifested by a diminished lymphocytosis and lowered globulin content of the C.-S.F. and by a reduction in the intensity of the blood W.R. First, the lymphocytes in the fluid decreased (91·9 per cent.); secondly, the blood W.R. diminished in intensity (65 per cent.); and then the protein content of the liquor became less positive (49 per cent.). A combination of all three changes occurred in 40 per cent. of the series.

The W.R. of the C.-S.F., the colloidal gamboge reaction, and the colloidal gold test were favourably influenced at a somewhat later period. The changes in order of frequency were W.R. of C.-S.F. 30 per cent., colloidal gold 30 per cent., and colloidal gamboge 20 per cent. A combined improvement in the globulin and cellular content and W.R. of the fluid occurred in 20·3 per cent. of all cases. Including the gold-sol test there was a combined improvement in 6·7 per cent. Negative W.R.'s were obtained in the C.-S.F. and the blood in 15 per cent. and 7·5 per cent. of the respective series. In two cases, or 5 per cent., were the liquor and serum W.R.'s concurrently negative.

Taking the 16 salvarsan cases as a separate series, the following percentages of readings of improvement in both fluid and serum were estimated: (1) diminished pleocytosis, 100 per cent.; (2) serum W.R. reduction, 68·7 per cent.; (3) lowered protein content 46 per cent. Combined changes (1, 2, and 3) occurred in 43·7 per cent.

Combined improvement in the cell count, protein content, and W.R. of C.-S.F. took place in 18·7 per cent., and with the gold-sol test in 6·2 per cent. of the whole series. The W.R.'s of the C.-S.F. and the blood serum were negative in 25 and 18·7 per cent. respectively—concurrently in both in 5 per cent.

We beg to acknowledge our indebtedness to Dr. R. M. Clark, medical superintendent of the hospital, for permission to place on record the results of these investigations. The Wassermann reactions of cerebro-spinal fluid and blood were kindly carried out for us at the Public Health Laboratory, Manchester, under the direction of Prof. W. W. C. Topley.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

JOINT MEETING OF THE SECTIONS OF MEDICINE, SURGERY, AND THERAPEUTICS AND PHARMACOLOGY.

AT a joint meeting on March 5th, Mr. CYRIL A. R. NITCH (President of the Section of Surgery) in the chair, a discussion was held on the

TREATMENT OF GASTRIC AND DUODENAL HÆMORRHAGE.

Mr. HERBERT J. PATERSON, opening the discussion, said that the surgical treatment of hæmorrhage from gastric and duodenal ulcers might be discussed in reference to two distinct groups of cases, the sudden acute hæmorrhages, threatening life itself, and chronic or recurrent hæmorrhages, less alarming in extent, but tending to produce a profound anæmia, which, if unchecked, might ultimately prove fatal. From a surgical point of view this classification seemed preferable to that in which a distinction was drawn between hæmorrhage from a so-called acute ulcer and hæmorrhage from a chronic ulcer, because it was not known that there was such a pathological distinction, and, if there were, it could not be recognised clinically. The duration of symptoms had no relation to the chronicity of an ulcer as seen in the operation theatre.

Acute Hæmatemesis.

Although aware of the danger of laying down hard-and-fast rules, he believed there should be no such thing as surgical intervention in cases of acute hæmatemesis—that operation during the progress of gastric or duodenal hæmorrhage should never be attempted. The collapse induced by loss of blood was favourable for arrest of hæmorrhage, but unfavourable for surgical intervention. It could usually be arrested by medical treatment; such patients, if subjected to operation, were exposed to added dangers, whereas without operation the probability was that they would recover. Two questions arose in this connexion: (1) the mortality-rate from hæmorrhage in cases treated medically, and (2) the mortality-rate in cases treated by immediate operation. Most clinicians were agreed that the mortality-rate from hæmorrhage in cases of gastric and duodenal ulcer treated medically was under 5 per cent. In the four series of cases collected by Lenhartz, Ewald, Wirsberg, and H. P. Hawkins the average mortality-rate was 3·8 per cent. With regard to the mortality-rate of the cases treated by immediate operation, Lindberg, in 1914, tabulated 83 cases with 30 deaths, a mortality-rate of 36 per cent. Those statistics might be called out of date, and more modern technique, especially with blood transfusion, might be claimed to secure better results at present, but he was not clear that there was ground for this optimism; at any rate, the results of surgical treatment were still indubitably inferior to the results of medical treatment. Through the courtesy of the surgical registrars of some of the London hospitals he had obtained some statistics as to immediate operation for acute hæmatemesis in recent years. In 19 cases there were 7 deaths (mortality-rate 36·8 per cent.). Obviously it was unfair to compare these figures with the mortality-rate in all cases of ulcer, whether they bled or not; they must be compared with the mortality-rate in severe cases of hæmatemesis. Hæmorrhage occurred in at least two-thirds of all cases of gastric ulcer, and was severe or recurrent in about 30 per cent. Calculated on this basis the mortality-rate of cases with severe or recurring hæmorrhage treated medically would be about 11 per cent. He thought this was probably an exaggeration, but it would be well within the mark to state that of the patients who bleed severely or repeatedly and are treated medically not more than 1 in 9 would die, while of those treated by immediate operation 1 out of 3 would probably die. No doubt

some surgeons by superior skill, aided by a considerable share of luck, might be able to show much better individual results than these. He said "aided by luck," for in a given case it was impossible to predict whether one could find, let alone deal with, the source of the bleeding.

A Series of Cases Personally Treated.

Apart altogether from statistics, he was convinced that the treatment of acute hæmatemesis by medical means was the wiser and safer course. It could not be emphasised too strongly that patients rarely died of a first hæmorrhage; repetition was the important thing. As for the argument: "This patient is bleeding; he will probably die; something must be done"—even were the premises true, he saw no reason for doing something which would probably make the patient's life shorter still. The case was quite different in acute intestinal obstruction, where without surgical intervention death was inevitable, so that operation was justifiable even in desperate cases. In hæmatemesis, on the other hand, operation might be the last straw for a patient who otherwise might recover. Up to the end of 1921 he had had under his care, or jointly with Dr. Soltau Fenwick, 40 cases where hæmatemesis was so severe that the patients were on the point of death, but all of them recovered with medical treatment; indeed, he had yet to see a death from hæmatemesis from a gastric or duodenal ulcer. All these patients were first treated medically, and in all but two gastro-jejunostomy was performed two or three months later. In four cases he could find no ulcer; the hæmorrhage was probably secondary to a diseased appendix; these were among his very early cases, and he now admitted that the gastro-jejunostomy was a totally unnecessary complication of appendicectomy. One patient had a slight hæmatemesis two months after operation, and no subsequent recurrence up to the time of death three years later from causes unconnected with the gastric condition. Another patient was readmitted into hospital a year after discharge in a moribund condition from a perforated jejunal ulcer. Thus the immediate operative mortality in this series was nil, and all but two of the patients were apparently cured.

Medical Treatment of Acute Hæmatemesis.

As regards the medical treatment of acute hæmatemesis, the important points were: (1) Absolute rest in bed; (2) Tripier's hot-water injections by the rectum (saline at 120°–130°F.); (3) an ice-pack to the abdomen; (4) nothing given by the mouth for at least four days, milk diet for two months, when some diluted beef essence might be added to the dietary; (5) small doses of morphia were valuable; (6) daily subcutaneous injection of a 10 per cent. solution of sterile gelatin in 40 c.cm. doses; (7) if vomiting or hæmatemesis continued the stomach should be washed out very gently with warm water, and after the lavage a dose of crystalline bismuth subnitrate given through the tube. It used to be taught that in hæmorrhage from the so-called acute ulcer, subsequent operation was unnecessary unless bleeding recurred, but the only safe rule was that an acute hæmorrhage required surgical treatment to prevent recurrence. The interval between the hæmorrhage and operation should be at least three months; if the patient was still anæmic transfusion of blood before operation was a valuable adjuvant.

Chronic or Recurrent Hæmatemesis.

For chronic or recurrent hæmorrhages operation should, as a rule, be deferred for two or three months after the last hæmorrhage, according to the patient's condition, medical treatment being carried out meanwhile. In large excavating ulcers, septic processes in the ulcer might play a considerable part in causing the hæmorrhage, so that it was important not only to rest the stomach but to keep it clean. If, *in spite of absolute rest*, there was further recurrence, operation might be considered, although personally he had never had to depart from his usual practice of delaying operation for two or three months. Operation, if decided upon, should be preceded by blood transfusion. There would probably be considerable difference of opinion as to the nature of the operation which should be performed for recurrent hæmorrhage. Ligature of arteries, excision of the ulcers, cauterising the ulcer combined with gastro-jejunostomy and partial gastrectomy had been employed; personally, he still pinned his faith to gastro-jejunostomy.

Some objected to gastro-jejunostomy on the ground that it was an indirect method of treating hæmorrhage, but it was the simplest surgical procedure to adopt, and had the great advantage that one started with a definite plan and was not tempted to do an extensive exploration which might turn the scale against recovery. If it failed it was time enough to adopt more drastic measures. He had had, alone or with Dr. Fenwick and Dr. Porter Parkinson, 84 cases in which there were recurrent attacks of severe hæmatemesis. In 82 of these hæmorrhage was due to a gastric or duodenal ulcer, and in all gastro-jejunostomy was performed. There were three deaths in this series, so that adding the 38 cases of gastro-jejunostomy before mentioned, there were three operative deaths in 120 operations, a mortality-rate of 2·5 per cent. In 4·2 per cent. there was a recurrent hæmorrhage of a trivial character, and in 90 per cent. no further hæmorrhage occurred after gastro-jejunostomy. He submitted that these figures justified the treatment adopted. He would offer one word of advice to his younger hearers: When called upon to treat a patient with hæmatemesis, they should take their courage in both hands and trust nature.

Discussion.

Sir WILLIAM WILLCOX said that no definite rule could be laid down for the treatment of severe gastric and duodenal hæmorrhage; the ætiology of each case must be separately considered, and treatment based on the provisional diagnosis. Some of the most severe hæmorrhages he had seen were in cases of cirrhosis of the liver, gastrostaxis, &c., in which the treatment usually adopted for a bleeding peptic ulcer might be contra-indicated. Certain principles of treatment might, however, be laid down, such as rest of the stomach and duodenum; he agreed with Mr. Paterson as to the danger of operation in the acute stage. Nothing should be given by the mouth for the first two or three days, or four or five days if hæmorrhage had been severe. With regard to local applications, he doubted whether the application of an ice-bag over the epigastric region was of much value. Morphine and its derivatives were undoubtedly useful; morphine was a powerful remedy for the control of peristalsis, but where hæmorrhage resulted from hepatic cirrhosis (due to alcohol, syphilis, &c.) the patient was strongly susceptible to the toxic action of these remedies, and the ordinary dose of ¼ gr. of morphine might cause death. Hepatic cirrhosis, and also chronic nephritis, contra-indicated the use of morphine; signs of hepatic or renal insufficiency should be sought before recourse was had to this drug. Another important factor in treatment was the promotion of the power of coagulation of the blood. He had adopted as a routine measure the intramuscular injection into the buttock of 1 gr. calcium chloride dissolved in 100 minims of distilled water. Serum injections were also useful; when a toxic cause was suspected, anti-streptococcic serum should be given. Blood transfusion was also of great value in counteracting hæmorrhage, and in some cases inhalations of carbon dioxide had been used with success.

Mr. A. H. BURGESS divided gastric and duodenal hæmorrhage into two types, one post-operative, the other arising from disease and independent of any operative procedure. Post-operative hæmorrhage followed operation (*a*) upon the stomach or duodenum, or (*b*) upon some other part of the body. In the former case prevention was more satisfactory than cure, and he stressed the importance of two points of technique: (1) All large vessels approaching the line of incision of the stomach should be under-run

with a suture and ligatured; and (2) the inner continuous layer of suture, taking up all the coats, should be closely applied, the needle passing ten times to the inch, and being drawn tightly. After gastro-enterostomy or partial gastrectomy, if the patient vomited, the vomited matter would always contain blood more or less altered, and usually already dark brown in the first vomit. If hæmorrhage continued the vomit would be brighter red; if this colour persisted and was associated with a rising pulse-rate some treatment should be adopted. He had seen three cases only which gave anxiety on the score of immediate post-operative hæmorrhage; the latter had ceased after the introduction of very hot water into the stomach—a method first introduced, he believed, by Rodman. The only fatal case he had had was after gastro-enterostomy for irremovable carcinoma of the pylorus; the main stem of the pyloric artery was shown post mortem to have been eroded in the floor of the malignant ulcer. Post-operative hæmorrhage after operations elsewhere than in the stomach and duodenum was rare, but had been met with after operations on almost all the abdominal viscera, and also elsewhere in the body. The mortality was high, having been put at 55 per cent.; the ætiology was obscure, but Rodman's view of a septic origin was generally accepted. Gastric or duodenal hæmorrhage other than post-operative might be grouped as associated, or not associated, with any gross local lesion in either viscus. Profuse hæmorrhage (gastrostaxis) might occur in the absence of such a lesion. He had three times operated for severe hæmatemesis without finding any gross lesion of stomach or duodenum. He had concluded that severe hæmorrhage from these viscera should not be surgically treated unless previous knowledge of the case, or definite relation of pain to the taking of food, pointed to a gross local lesion. Profuse hæmorrhage from chronic gastric ulcer was usually either quickly fatal from erosion of a large artery, or, if once arrested, did not tend to recur soon and repeatedly, as did that from a duodenal ulcer. He had no belief in "indirect" arrest of hæmorrhage by gastro-enterostomy. If operation were undertaken at all it should be a direct attack on the bleeding ulcer—its separation from pancreas or liver, and its destruction by excision or cautery.

Dr. A. F. HURST believed that hæmorrhage from gastric and duodenal ulcers was far less often fatal than was generally supposed. He had never had a case where death resulted, and only once had he had to call in a surgeon to save the patient's life. Dr. J. J. Coneybeare had investigated the post-mortem records of all cases of fatal hæmorrhage from gastric and duodenal ulcers (in the absence of cirrhosis of the liver) at Guy's Hospital between 1911 and 1920 inclusive. The total number was 23—i.e., 2·6 deaths a year if allowance was made for the fact that no post-mortem examinations were made in 12 per cent. of patients dying in the hospital. The 23 autopsies constituted 0·37 per cent. of the total number performed in the ten years. Only 13 of the 23 died from hæmorrhage without having undergone some previous operation; as about 600 cases were admitted, during the period in question, for hæmorrhage from an acute or chronic ulcer, the mortality of severe gastric and duodenal hæmorrhage was about 2·5 per cent. The most important factor favouring the cessation of this hæmorrhage was complete immobility; the patient should be reassured about his condition, and should be given repeated doses of morphia to keep him drowsy. Complete starvation for 48 hours should be secured, after which the ordinary strict treatment with diet, alkalies, belladonna, and olive oil should be begun. When hæmorrhage was severe, the rapid distension of the stomach resulted in more or less complete evacuation by hæmatemesis, followed by contraction, which might cause the hæmorrhage to cease. He used ice-cold water to empty the stomach. The danger of recurrence depended upon the digestion of the clot by gastric juice, the secretion of which was called forth by blood as by any other food. For this purpose alkalies must be given, which did not, like sodium bicarbonate, stimulate the secretion of more juice after neutralising an equivalent amount of acid, or give off large quantities of carbon dioxide, which distended the stomach and stimulated peristalsis. Oxide of magnesia was almost ideal from that point of view; it was most conveniently given as emulsio magnesiæ (B.P.C.). At the earliest possible moment after a hæmorrhage the patient's blood should be grouped and a donor found and kept at hand. Hæmoglobin estimation should always be done. He believed that the only indication for operation in the acute stage was severe and persistent hæmorrhage in an elderly person, with a long history pointing to the presence of a chronic ulcer, whose arteries were too degenerated for satisfactory plugging by thrombosis. Neither the occurrence of hæmorrhage in the past, nor the danger of future hæmorrhage in a patient who had not previously bled, should be regarded as indicating surgical rather than medical treatment for a chronic ulcer. The only definite indications for surgery were, in his opinion, perforation, hour-glass contraction, and pyloric obstruction, neither of which should ever occur, in his opinion, with early diagnosis, strenuous and prolonged treatment, and proper after-treatment.

Mr. R. P. ROWLANDS thought that most physicians and surgeons were agreed that operation was necessary for repeated bleeding of a chronic or duodenal ulcer. About 25 per cent. of these chronic ulcers caused obvious and severe bleeding; the latter was not the direct cause of death in more than 2 per cent., but by lowering the vitality it was an indirect cause. With an acute ulcer (particularly in a young person) there was every hope that thorough medical treatment would effect a cure, but recurrent hæmorrhages constituted a different class: when there was good evidence of a chronic gastric or duodenal ulcer, operation should be performed. Nowadays, expert radiography hardly ever failed to discover the crater of an ulcer, or a deformity due to it. The ulcer itself must be attacked; if the patient was very ill, the arteries should be tied and the ulcer invaginated with careful catgut sutures. A duodenal ulcer on the posterior wall should be cauterised, and gastro-duodenostomy should be done in preference to gastro-jejunostomy. It was a bad thing to operate during hæmorrhage, but hæmorrhage must not be said entirely to contra-indicate operation.

Resumed Discussion.

The discussion was then adjourned. On its resumption Dr. ROBERT HUTCHISON (President of the Section of Medicine) took the chair.

Dr. IZOD BENNETT noted that all the speakers had emphasised the fact that immediate treatment of all acute cases of gastric and duodenal hæmorrhage should be left in the hands of the physician. Cases were, however, continually sent into surgical wards of hospitals, showing that students and newly-qualified practitioners believed that a surgical treatment existed. Further to emphasise the fact that treatment was medical he enumerated four points: (1) The diagnosis was often very obscure; (2) the object of urgency was the prevention of the patient's immediate death, and of 61 cases he had examined post mortem 25 had died as a result of perforation, 13 from hæmorrhage, and 23 as a result of surgical intervention, so that operation caused more deaths than did hæmorrhage; (3) the patient after a severe hæmorrhage was not in a condition to stand the shock of operation; and (4) in the series referred to, hæmorrhage was responsible for 21 per cent. of all deaths due to gastric and duodenal ulcer. The mortality in cases medically treated was less than 5 per cent. Some kind of resection was the commonest form of surgical treatment to-day; not enough operators had given results of surgical treatment for any just comparison to be made, but unless such results showed a mortality below 5 per cent., resection operations were not justified. Absolute rest and prolonged starvation by the mouth were necessary in medical treatment; gastric lavage

he considered dangerous. Intravenous administrations of blood or saline were to be avoided, on account of the danger of raised blood pressure. When the probability of hæmatemesis was past, the problem changed, and the fact of hæmatemesis having once occurred might be an additional reason for surgical treatment.

Mr. G. GORDON-TAYLOR said that surgical treatment of acute ulceration of the stomach was never required, but chronic ulceration was a different matter. Some cases of elusive ulceration of stomach or duodenum seemed to be absolutely fatal diseases, because of the erosion of arteries. Treatment should be prophylactic, before the ulcer attained sufficient size to produce fatal consequences. Once a particular hæmorrhage had started it was wise to wait until it ceased, and then interfere as soon afterwards as possible, remembering that erosion of a large artery might occur very soon. He had operated when hæmorrhage was actually taking place, and had succeeded in several cases in a direct attack upon the ulcer as soon as hæmorrhage had stopped. The operator should be amply provided with all available methods of resuscitation, including facilities for repeated blood transfusion.

Dr. P. HAMILL described arrest of the hæmorrhage as the fundamental therapeutic principle. Gastric or duodenal hæmorrhage differed from hæmorrhage from the surface of the body in that one only knew that the patient had bled, and that the bleeding-point was not susceptible to pressure. He had never seen an immediately fatal case. Treatment, assuming a diagnosis of hæmorrhage from an ulcer, was of a patient who had bled, might be bleeding, or might bleed again. Complete tranquillity of the patient was necessary, and contraction of the musculature of the stomach could be aimed at. He believed that an ice-bag did help to arrest hæmorrhage; it undoubtedly eased the patient's mind by relieving soreness. The administration of chalk combined with magnesia was useful for the promotion of coagulation at the bleeding point. As regards the washing out of the stomach with cold water, he had had no occasion to use a method so drastic. The stomach-tube did not enhance tranquillity. Treatment was essentially medical, but cases occurred where surgical measures might be required; many of these were duodenal, and some were in elderly persons with sclerosed vessels, the ulcer perforating through into a vessel.

Mr. C. H. FAGGE could not agree with previous speakers concerning the danger of gastric and duodenal ulcers. He had seen W. J. Mayo excising duodenal ulcers, and since that time had himself excised every gastric or duodenal ulcer when there had been hæmorrhage. Some operation dealing directly with the ulcer was, in his opinion, the right thing. In the past few years he had seen two patients who died of hæmorrhage whilst surgical treatment was being considered. He had recently operated on a patient for a medical colleague who thought surgical treatment offered the only chance of saving the patient's life. He had opened the abdomen after blood transfusion, and had found a thickened pylorus, and a large ulcer on the lesser curvature, which he excised, discovering a large vessel in its base; he did not believe that medical means could have stopped that hæmorrhage. He had hoped to learn something regarding hæmoglobin estimation—what to do in cases where rest and other treatment failed to raise the hæmoglobin beyond 30 per cent., and whether it was then wise to interfere surgically.

Prof. G. E. GASK said that until three years ago he would have endorsed Mr. Paterson's opinion concerning the treatment of a patient bleeding from a gastric ulcer, but since that time his opinion had been changing. He had seen, post mortem, cases that had died of hæmorrhage with large open vessels in the ulcer. No medical treatment could stop hæmorrhage in such cases; ligature was necessary. Transfusion was very valuable. The technique of gastric surgery had improved, and he now believed that a certain number of these cases could be saved by surgery. The ideal thing was that gastric and duodenal ulcers should be prevented, but, as things were, they had to deal with a certain number of moribund cases of these conditions. He instanced a case where a hard, firm blood-clot distending the stomach, had to be removed by hand. He could not agree with Dr. Bennett that transfusion made patients more likely to bleed.

Mr. GARNETT WRIGHT said that all records of cases of hæmorrhage not due to ulcer should be removed from the discussion, for they falsified statistics. Diagnosis of these ulcers depended on the clinical history. Medical treatment was proper in the first instance, but in some cases hæmorrhage recurred repeatedly, and it became their duty to estimate which patients might be operated upon. He had operated in seven cases, with three deaths and four recoveries; he had never operated after a single hæmorrhage, and thought operation should, if possible, be deferred until bleeding stopped.

Dr. HUTCHISON, speaking from the chair, said that certain things had emerged from the discussion. One was that hæmatemesis was not considered to be very dangerous; he thought some speakers had tended to under-estimate that danger, having himself seen many fatal cases of hæmatemesis. Another point was the importance of accurate diagnosis. Surgery had been narrowed down to cases of hæmorrhage for chronic ulcer of stomach or duodenum. He believed that there was no medical treatment for hæmatemesis, beyond keeping the patient quiet. He had never dared to wash out the stomach and run in adrenalin, &c. Most of the earlier speakers had opposed surgical treatment of hæmorrhage from gastric and duodenal ulcers, and some of the later speakers had urged that some of these ulcers should be directly attacked. He believed that with modern facilities it should be possible to make a direct attack on the bleeding point.

Mr. PATERSON briefly replied.

JOINT MEETINGS OF THE SECTIONS OF THE STUDY OF DISEASE IN CHILDREN, NEUROLOGY, OBSTETRICS AND GYNÆCOLOGY, AND ORTHOPÆDICS.

BIRTH INJURIES.

A MEETING of these sections was held on March 6th, Dr. CUTHBERT LOCKYER presiding, when a discussion on Birth Injuries, with Special Reference to Intracranial Injuries with Hæmorrhage, and to Nerve Injuries, was held.

Mr. EARDLEY HOLLAND, who opened the discussion, drew attention to the astounding frequency of intracranial injury in cases of stillbirth and of neonatal death. This was a disturbing fact for obstetricians, since in so far as the injuries were mechanical in origin, they were largely preventable. The conditions were not always immediately, or even remotely, fatal, and there was reason to suspect that those children who survived might bear the stigma of birth trauma in the form of various nervous and physical maladies. The frequency with which hæmorrhage had been found varied, according to different observers, between 21 per cent. and 55 per cent. of cases of stillbirth and neonatal death examined, the last-named figure being that found by Mr. Holland. Hæmorrhage might be (1) subdural, (2) ventricular, (3) in the cerebral substance. Again, it might be severe, moderate, or slight, and was often diffuse rather than localised. Subdural was commoner than ventricular hæmorrhage. As to its ætiology, the hæmorrhage might be (*a*) traumatic, or (*b*) asphyxial. Traumatic hæmorrhage was usually accompanied by tears of the tentorium cerebelli or falx cerebri, and asphyxia by the signs of fœtal asphyxia, but this distinction did not always hold, because many cases with tears were accompanied by fœtal asphyxia. Possibly the initial traumatic hæmorrhage caused circulatory disturbances that led to severe asphyxia, and it was also likely that asphyxia was an important contributory cause of traumatic hæmorrhage, since engorged blood-vessels were more

likely to be ruptured by a superadded mechanical strain.

Traumatic Hæmorrhage.—To appreciate the mode of origin, it was necessary to know how the fœtal head behaved when acted on by the forces of labour. The fœtal head was a fragile object, which displayed a remarkable combination of qualities which enabled it to resist injuries, with defects which disposed it to suffer them. The wonder was the large number of fœtuses that reached the world alive and uninjured. Cranial stress consisted of two elements: (1) General compression of the whole head, and (2) simple longitudinal compression. The alteration of shape was brought about partly by the displacement of the plastic bony vault as a whole, and partly by the bending of the individual bones which compose it. Mr. Holland showed slides illustrating how the dura mater septa are attached to the cranial bones, forming a close arrangement of stays or ligaments. When the head alters its shape, alterations in tension of the septa are inevitable owing to the nature of the attachments to bones. Excursion and bending of bones is resisted by the tension of the septa, just as the swaying of a mast is resisted by the tension of its stays. If the alteration in shape is too great, the septa tear and this permits more extreme alteration in shape, and dangerous disturbances in other intracranial contents. These septa exert a protective function against excessive alterations. Support was lent to this theory by the special strengthening bands and fibres arranged on lines where stress is likely to fall. Tearing of the tentorium and falx was clear evidence of excessive cranial stress and formed the best and simplest means of estimating its degree. Tears lay in the area of greatest stress, usually at the free border of the tentorium near the junction with the falx, less commonly in the falx. All degrees of tear might be present. These bands acted as a restraining influence in keeping the fœtal head symmetrical, and when one was badly torn, the head sometimes became oblique. Tears were found by Holland in 48 per cent. of stillbirths, and by other observers in percentages varying from 24 to 60. Schaefer found them in 91 per cent. of stillbirths after difficult forceps delivery.

Mode of Origin and Source of Hæmorrhage.—The actual tear was not dangerous. Mr. Holland's view was that hæmorrhage mostly came from the vein of Galen or its tributaries, since any movement of the apex of the tentorium was necessarily transmitted to this vein, whose fixed point was at its entrance to the straight sinus, but this was, of course, not the only source of hæmorrhage. Circumstances which determined excessive cranial stress were (1) disproportion between the head and the fundus, or deficient flexion and great rigidity of separate parts, (2) forceps, if used too early with too great force, or if delivery were too rapid. Misplacement of forceps might cause damage, and the use of forceps to deliver a premature fœtus had its dangers. It was of great importance whether the stress was gradual or rapid—for example, tearing was found in 75 per cent. of dead fœtuses delivered by breech, and F. J. Browne stated that this injury was 15 times more likely to occur in breech than in vertex presentations. Similarly, rapid birth, spontaneous or following pituitary, was also dangerous. A soft and plastic premature head was more likely to suffer injury than the firm head of the full-term child. The fact that tearing of tentorium and hæmorrhage could occur after apparently a normal labour, was difficult to explain; possibly some of these cases were caused by a too zealous guarding of the perineum, especially by strong forward pressure forcing the occiput against the symphysis.

Fœtal Asphyxia and Intracranial Hæmorrhage of Asphyxial Origin.—When the circulation in the cord was obstructed or the placenta separated or degenerated, fœtal asphyxia resulted, and if it continued long the fœtus died. Post-mortem signs of asphyxia were found in 30 to 40 per cent. of fœtuses who had died during labour. Observers differed in regard to the relative frequency of traumatic and asphyxial hæmorrhage. In Mr. Holland's series of 92 cases he placed 75 as traumatic, 17 as asphyxial. Post-mortem differentiation was not always possible, and often the conditions coexisted.

The Pediatrician's Standpoint.

Dr. H. C. CAMERON discussed first the symptomatology of subdural hæmatoma in the newly born. In almost all cases there was a bulging fontanelle, and the cerebro-spinal fluid was under high tension and blood-stained. The ophthalmoscope in almost half the cases was said to show punctate hæmorrhages, more rarely œdema of the disc. An increased rigidity and spasticity of limbs, often with opisthotonos and trismus, was common, and either generalised convulsions or localised twitchings. There might be somnolence or coma, or persistent crying and restlessness with all the appearances of pain. Some interference with the respiratory rhythm was the rule. There might be asphyxia at the moment of birth, and respiration, when established, might remain shallow and halting. The suction reflex was often absent. It was clear that the life of such infants was precarious. Of Dr. Cameron's eight cases all were fatal, but he was convinced that in cases of lesser severity the condition was compatible with life. So long as our powers of diagnosis only enabled us to recognise the severest grade the doubt must exist. He advocated the routine use of lumbar puncture and of the ophthalmoscope in the newly born and a careful clinical examination, now often confined to noting the colour of the fæces. If recovery took place the long latent period before further symptoms developed might be accounted for by the fact that the pyramidal tracts only gradually become medullated during the first year; delay in the transition from the spastic uncontrolled movements characteristic of the newly born to that degree of voluntary control of lips, tongue, hands, and feet which the normal infant achieves might not be obvious to the parents until the failures to walk or grow at a year or more proclaimed it. The infant whose cortex had been damaged lagged far behind the normal in development upon the sensori-motor side, and infantile education proceeded largely along these paths; the initial delay in development was much greater than the ultimate loss. In later childhood improvement might be rapid. Dr. Cameron dwelt on the high plane of general character and power of concentration found in these children, and the improvement in mental condition following orthopædic treatment. They formed a group apart, which seemed to him clearly separated from cases of spastic idiocy due to a developmental deficiency of cortical neurones. That Little was right in contending that the cause was to be found in cortical hæmorrhage at birth, he believed strongly, although this condition might not be the only or invariable result of such an accident.

Dr. JAMES COLLIER said that he could conceive of recovery from hæmorrhage in nearly every one of the regions demonstrated by Mr. Holland, except from hæmorrhage in the brain substance. The origin of infantile spastic paraplegia from meningeal hæmorrhage was now discredited, though some few infantile spastic states might result from asphyxia. It remained to be considered why abnormalities at birth were associated with spastic diplegia. He had set out fully in his presidential address to the Neurological Section[1] his view that both these conditions were expressions of a deeper-lying pathological influence which had disturbed the mysterious relationship between mother and child. He then briefly reviewed the history of the supposed connexion of birth injuries with infantile spastic paralysis. He pointed out the common occurrence of varying degrees of subarachnoid hæmorrhage in the infant during the process of birth and argued that minor degrees of such hæmorrhage are unassociated with any detriment to the child, while major degrees had an especial symptomatology. He criticised the opinion that asphyxia neonatorum is dependent upon meningeal hæmorrhage.

[1] THE LANCET, 1923, ii., 1129.

Birth Palsy.

Mr. H. A. T. FAIRBANK said that in his series of 98 cases (males 56, females 42) 93 were unilateral and 5 bilateral, making a total of 103 arms paralysed. The evidence seemed to point strongly to the traction theory as being the correct explanation of the paralysis, if by traction were meant any position which involved deviation of the head away from one shoulder, which necessarily put strain at the upper cords of the brachial plexus, as well as direct traction of the arm, which was only exceptionally the cause. His reasons for favouring the traction theory had been set out in the *Journal of Orthopædic Surgery* (vol. ii., No. 5, May, 1920). Birth palsy was about four times as common in head as in breech presentations, the figures in his series being 71 vertex and 19 breech, two in which turning forceps were employed, while in six no details of the birth were obtainable. As a rule, but not invariably, labour had been difficult, and instruments had been used in half the cases. Of six plexuses explored, in five he had found evidence of more or less serious damage to the fifth and sixth cervical nerves. The paralysis was usually of the upper arm type, affecting the muscles supplied by these nerves. The vast majority of cases recovered more or less completely, certainly to an extent which contra-indicated operation on the plexus. The typical palsy was well known. Obvious signs of recovery were usually present three months after birth when the case had been properly treated. The treatment consisted in leaving the arm in a position which relaxed paralysed muscles, and daily massage and passive movements of all the joints to prevent contractures. The most important was the use of a splint (which was demonstrated) to hold the arm abducted at the shoulder and the forearm vertical and supinated. These cases showed a marked tendency to contractures, probably due to want of voluntary activity, in spite of the recovery of the paralysis. If there were no signs of recovery in three to six months, confirmed by electrical stimulus under an anæsthetic, the plexus should be explored. Nerve-grafting has been tried without real benefit; nothing but secondary suture of the nerves, or excision of scarred portions, followed by suture, was of any use.

Posterior Subluxation of the Shoulder-joint, by no means rare in children, was secondary to the paralysis, and was inevitable if the case was untreated. The subluxation did not develop unless a considerable degree of recovery had taken place. The deformity consisted in slight flexion and abduction of the humerus with marked internal rotation. External rotation was impossible, and this prevented the power of supination from being made use of; in fact, the hand was hardly used at all. The cases in which the displacement was reducible were treated by daily manipulations, and the use of the same splint as is used in the paralytic stage. In irreducible cases forcible attempts at reduction under an anæsthetic were unsatisfactory, and the method of choice was by open operation, the division of the junction of the subscapularis muscle, and the contracted anterior part of the joint capsule. Mr. Fairbank said that he now fixed the arm in abduction after operation, and in external rotation, and replaced the plaster cast after three or four weeks by a metal abduction splint which allowed of massage and active and passive movements. Although the other movements of the shoulder might show little improvement, outward rotation was always possible after operation, and this allowed the hand and forearm to be used. The tendency to adhesions and contractures of all joints, not only of the shoulder, still persisted in these children and had to be kept constantly in mind.

The Localisation of Hæmorrhages into the Brain Stem.

Dr. THOMAS LUMSDEN described the effects of hæmorrhage into the brain stem experimentally produced in mammals. It was reasonable to assume that hæmorrhage into the infantile brain stem must have similar results, and this had been confirmed by serial sections of two human brain stems into which hæmorrhages had occurred at or just after birth. The results observed corresponded accurately with the experimental findings. Before death these infants showed the type of breathing described as apneustic.[2] The effects of serious hæmorrhages at the levels of origin of the fifth, eighth, and tenth cranial nerves were found to correspond exactly with the results of section of the brain stem just below the level into which the hæmorrhages took place. The alteration in the position of the cephalic contents sometimes occurring during birth, which Mr. Holland had described, must involve a considerable alteration in the position of the brain stem, and here was a possible explanation of the occurrence of deep hæmorrhages. By noting certain alterations in the character of the breathing it was possible to predict ante mortem the exact level of the damaged area and to have some grounds upon which to base a prognosis, and Dr. Lumsden described the experimental evidence for the existence of four respiratory centres, which enable us to locate hæmorrhages into the brain stem. If after an intracranial hæmorrhage the normal type of breathing continues we may conclude that there is no serious injury to the brain stem. If the respiration is apneustic in type the hæmorrhage is in the pons. If only expiratory spasms and gasping occur the damage is at the level of the striæ, and if gasping alone is seen then the dominant hæmorrhage is just above the "noeud vital," near the apex of the calamus scriptorius. As to treatment, this must be immediate if it is to be of any use. In animals artificial respiration was most effectively achieved by pumping or blowing into the lungs oxygen to which 5 per cent. of CO_2 has been added, the latter in order to stimulate the respiratory centres. If the heart had stopped cardiac massage must be instantly performed.

As to prognosis, the lower down the brain stem the more serious were the effects of hæmorrhage, but recovery was possible whatever the level affected if the hæmorrhages were small and not very numerous. If in the cat the heart stopped so that the cerebral circulation ceased, unless it could be restarted within five minutes the cerebral hemispheres would not revive. If the circulation had ceased for 15 minutes the whole of the brain stem was irrevocably dead. So that while in the cat the heart might be restarted by massage and injections even after it has ceased beating for an hour or more, the central nervous system had been long dead, and could never resume its activity though the heart might continue to beat for several hours. It seemed probable that in man these viability periods (5 to 15 minutes) would be yet shorter than in the cat, so that most of the cases of attempted revival reported in the press were of necessity quite hopeless and unavailing.

Dr. GILBERT STRACHAN said that in 100 cases of stillbirth examined by him dural laceration was found in 23, and in 50 cases of neonatal death a similar lesion was present in 12; the total was thus 35 out of 150 cases of stillbirth or neonatal death, approximately 23 per cent. The laceration was accompanied by hæmorrhage of varying degree in 26 out of 35 cases in which tears had been found. In a number of cases in this series the bleeding did not appear to be sufficiently extensive for such an origin as Mr. Holland suggested (vein of Galen), since the hæmorrhage was represented by only a little clot. Dr. Strachan also found the liability to tentorial laceration, which was by far the commonest cause of intracranial hæmorrhage, was markedly increased in breech presentations, and emphasised the desirability of prophylactic external version in all breech cases, especially in primiparæ. In some of the neonatal cases who lived from one hour to

[2] An apneusis is a prolonged inspiratory tonus or holding of the breath. A gasp is a sudden involuntary incoördinated inspiration. Dr. Lumsden's researches are published in full in the Journal of Physiology, lvii., 153 and 353; lviii., 81 and 111.

four days the infant presented no abnormality at birth, and death in these cases usually occurred suddenly. Generalised twitchings and convulsions were seen in a number of cases, in others inability to suckle, while a drowsiness deepening to coma was present. In the majority of cases under discussion obstetrical difficulty was present in varying degree.

Dr. BERNARD MYERS described briefly the case recorded by himself and Dr. W. D. Kirkwood in THE LANCET of July 14th, 1923, which supported the experimental evidence given by Dr. Lumsden. He pointed out that since this condition was not well recognised medico-legal trouble might arise, and it should be borne in mind when the case against the parents or nurse looked suspicious.

Mr. D. M. AITKEN gave instances of the immense benefit to children with spastic paraplegia, not only in their physical but in their mental condition, which followed re-educative treatment by orthopædic surgeons.

Mr. BRIGHT BANISTER said that from the obstetrical standpoint three considerations arose: (1) the causation of injuries; (2) the fatalities attending them; (3) the possibility of their prevention. As to causation, he agreed with Mr. Holland that no such hurry as had been at one time taught was essential in the delivery of living babies in the breech presentation. It was unnecessary and dangerous to attempt to deliver the head in under five minutes from the time of the birth of the umbilicus. In one case in his experience 14 minutes' interval had elapsed and the infant breathed normally after a few minutes. As to causation of birth palsy, traction exerted on the head after birth in order to deliver the anterior shoulder was a point not to be forgotten. Too much force used here might well cause injury. As to prevention, the obstetrician could only continue his irksome duty of urging practitioners to forestall difficulties instead of waiting to overcome them.

SECTION OF LARYNGOLOGY.

SUPPURATIVE DISEASES OF THE SINUSES.

A MEETING of this section was held on March 7th, under the presidency of Mr. H. J. BANKS-DAVIS. Instead of the usual clinical meeting, a discussion was held on the subject of Suppurative Diseases of the Frontal, Ethmoidal, and Sphenoidal Sinuses.

Mr. MUSGRAVE WOODMAN introduced the subject. He said suppuration of the sinuses enumerated in the title constituted border-line territory. Above it the physician held sway, and often confirmed his diagnosis on the post-mortem table. From below the rhinologist looked up along the dark passages and around corners. Between the two lay a territory as yet very imperfectly explored. Such could only take place by collaboration and accurate histological examination on the part of those who dealt with either side. Comparison of the frontal sinus with the gall-bladder was an apt one; it was a cavity drained at its lowest part by a tube leading to a larger cavity, and its illnesses largely depended on the conditions in the duct and the morbid processes which surrounded that duct. Dr. Logan Turner was insistent that before any operation on the frontal sinus was contemplated a complete X ray examination should be undertaken to disclose its pathological anatomy. Frontal abscess, of which he was exhibiting a specimen, was a somewhat rare complication. An important complication was osteomyelitis, which was well known as a sequel of any operation in the region of the frontal sinus; it did not arise after operations on the antrum, and but rarely in connexion with procedures on the ethmoid. The mucous membrane lining was continuous with that of the nose, the bony walls were continuous with the nasal sinuses, and the abnormality was in the blood supply. There were no veins in the frontal sinus itself. The free anastomosis existing between the angular veins, the superior longitudinal sinus, and the emissary veins of the meninges, suggested it was the vascular connexion which had much to do with the occurrence of osteomyelitis in the frontal sinus. With regard to neuralgia of the frontal sinus, many of these cases did not come to the rhinologist. One case he quoted was that of a man who was well until five years ago, when he began to have nasal catarrh. Every winter thereafter he had a sense of oppression and discomfort over the right side of his forehead. Last winter it culminated in a violent attack, and he sought advice. Mr. Woodman at the operation found pus in the frontal sinus under considerable tension.

Concerning the methods of treatment of frontal sinus conditions, those who knew the intranasal approach to the sinus were aware of the cases in which that was suitable and what were its limitations; they also knew its complications. But it was very desirable to know, without bias, what type of case was most suitable for the external operation. The best type of external operation had now been placed beyond question; it was that devised by Mr. Walter Howarth, a member of the section. Mr. Woodman regarded it as a perfect operation. Was an external operation necessary in all cases? What were its complications? Did osteomyelitis arise from it? It was less likely to arise as, by this operation, the bone was approached through the floor. It was desirable also to know what were the results of the operation and the difficulties of drainage which had been encountered. With regard to the ethmoid bone, it was a spongy bone, and a source of permanent and late infection. Infection spreading up the nose receded again and left infecting organisms in the loculi. The ethmoid was divided obliquely into an antero-inferior portion and a postero-superior portion, which were distinct, influencing respectively the frontal sinus in front and the sphenoidal fissure behind. The normal ethmoid bone had a large number of perforations, due to the passage through it of vessels. The difference between the dura mater and the floor of the anterior fossa of the frontal sinus was very considerable. Frontal suppuration would cause extra-dural abscess, or frontal lobe abscess, but it did not often cause generalised meningitis. He had seen two cases of encephalitis lethargica in which every sinus in the head was full of pus, and the patient seemed to be dying. The physician and neurologist were met in consultation, but no post-mortem examination was allowed. A series of investigations were much wanted on these meningitis cases which died following sinus involvement; many of them had had persistent sinus trouble which had been unsuspected.

Mr. Woodman said he was convinced that cavernous sinus thrombosis arose primarily from the ethmoid, not from the sphenoid. It would seem to be the right treatment to start a complete exenteration of the ethmosphenoid on one side, and so approach the cavernous sinus and turn out the clots. In the ethmoid a subtle form of neuralgia was met with, and its origin was apt to be missed. He related a case of it. It was desirable to know whether it was necessary to remove all the ethmoid cells, or whether the opening up of a certain number was sufficient. In the former event he discussed the best procedures. The sphenoid was a plain cavity; he showed a slide of it, indicating the close proximity of the palatine ganglion, the vidian nerve, and the middle turbinate bone to each other. The slide showed how disease in the posterior cells could exert its bad influence. The sphenoid he considered was more often maligned than it deserved to be; the source of trouble was more often the ethmoid. The importance of the sphenoid lay in its relationship to the optic foramen and the vidian canal. Sluder's experiments showed that the first and second divisions of the fifth nerve could be reached by cocaine, and therefore by sepsis and by drugs. He exhibited slides to illustrate the danger of operating on the ear for sphenoidal disease when sphenoid pain was referred behind the ear. Suppuration in the sphenoidal cavity might cause dilatation of the pupil and visual symptoms. In conclusion, Mr. Woodman referred to the connexion of the sinuses with the pituitary. It was now well known that a source of sepsis anywhere in the body had a marked influence on the

thyroid gland; therefore, in view of the permeability of the sphenoidal sinus by drugs, he asked whether it was not probable that in latent or active infection of that sinus the pituitary itself would be infected. He thought there was a wide field for research in connexion with the pituitary gland; and that meningitis and neuralgia also stood in need of a good deal of investigation.

Dr. W. T. GARDINER gave a clear description, with the aid of lantern slides, of the method carried out by Sluder in opening the ethmoid and sphenoid intranasally. It was carried out under local anæsthesia.

Dr. DOUGLAS GUTHRIE described his efforts to ascertain the degree of friability of the cribriform plate, and its relationship to the anterior ethmoidal cells; also how easily the cribriform plate could be broken into. He found that the anterior part was the more easily penetrated. It constituted an argument for the Sluder operation. In 74 per cent. of 200 skulls he found the ethmoidal cells rose above the cribriform plate, and that the olfactory groove was deep; shallow in the remaining 26 per cent.

Mr. HERBERT TILLEY referred to cases of osteomyelitis of the frontal bone, apart from operations on the sinus. In opening the sinus externally he urged that no sharp curetting instrument should be used, because of the danger of opening some of the small diploe and allowing some infection to enter. Sphenoidal sinus diseases he considered to be very common. He discussed the whole subject at some length.

Mr. ERIC WATSON-WILLIAMS showed skiagrams of some cases of frontal sinus disease, and related their symptoms and treatment.

Dr. LOGAN TURNER (Edinburgh) said that last spring he sent a questionnaire on the subject of intracranial complications to the surgeons in this country, especially with reference to osteomyelitis. These complications were divided into two groups: (1) Spontaneous, (2) post-operative. There were 125 returns, of which 77 were spontaneous, 48 post-operative, the former occurring in patients under 30 years of age, in two the patients were under 10; 34 were complications of acute and subacute sinus suppuration, 40 complicated chronic sinus suppuration. It would be valuable if there could be returns of the percentage of complications which arose in sinus suppuration, so that they could be compared with the intracranial complications arising in aural suppuration. Complications occurred where one sinus alone was affected in 37 per cent. of the cases; where two or more sinuses were involved the percentage was 62. Of 71 cases the frontal sinus was involved in 41, the sphenoidal in 19, the ethmoidal in nine, the maxillary in two. The post-operative complications occurred mainly after operations for chronic sinus suppuration—namely, 89 per cent.; only in 10 per cent. of acute sinusitis. Osteomyelitis occurred in 58 per cent., and it was not by any means only a sequel of the external operation. He agreed it might be started after operations on the antrum. Osteomyelitis followed frontal sinus operation in three of eight intranasal operations, and in 12 of 20 frontal bone operations.

Sir STCLAIR THOMSON said that in his clinic there had been a considerable number of what he regarded as spontaneous cases of osteomyelitis, many of whom gave a history of having recently been in a swimming bath. These spontaneous cases responded favourably to operation, and in that particular were in favourable contrast to the others.

Mr. W. S. SYME expressed his satisfaction with the Sluder operation, and related his operative methods. He uttered a warning against perforating the sphenoidal sinus from the centre of the anterior wall; one should have great respect for the dura mater covering the floor of the cranial cavity. In dealing with the ethmoidal cell, the great need was thoroughness.

The PRESIDENT thought sinus cases were often operated upon in hospital too soon.

Mr. G. W. DAWSON agreed with the President.

Mr. WOODMAN, in reply, said he did not think that 50 years hence the Killian operation would be required or performed at all; he considered Mr. Howarth's operation far superior. With regard to the danger of meningitis in connexion with ethmoidal disease, he agreed it was a danger, but in one or two cases of malignant disease he had exposed the dura of the anterior fossa freely, and in one case he accidentally cut it, and cerebro-spinal fluid came out; but he stitched it up, applied iodine, and saw that it was well drained, and the patient did not even have a rise of temperature. The condition he had to deal with in that case was not only malignant, but also septic; he did not think malignant disease occurred in the upper part of the nose without sepsis. But the greatest care must be taken not to perforate the cribriform plate or any part of the floor of the cranial cavity.

A number of patients and specimens were shown by various members.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

Surgical Treatment of the Stomach.

A MEETING of this section was held in the Royal College of Physicians on Feb. 29th, Sir WILLIAM I. DE COURCY WHEELER, the President, being in the chair.

Mr. JAMES SHERREN delivered an address on Observations of Disease of the Stomach and Its Surgical Treatment, which was published in THE LANCET of March 8th.

The PRESIDENT said that the first question to be settled was the question of diagnosis of gastric ulcer. Surgeons often hesitated for sound reasons to make the diagnosis unless supported by a positive X ray picture. He alluded to the manner in which extra gastric lesions mimicked ulcer of the stomach, and pointed out that although hæmatemesis might be a brick in the diagnostic building, it arose from so many causes other than ulcer that it was by no means conclusive. He agreed that the association of chronic ulcer of the stomach with malignant disease was very definite and close, but thought it must be difficult to arrive at a figure representing the percentage of chronic gastric ulcers which became malignant. The President strongly agreed with the teaching of Mr. Sherren, Sir Berkeley Moynihan, and others in connexion with the necessity for partial gastrectomy in the treatment of many forms of chronic ulcer, and supported the view that the convalescence was uneventful and the mortality inconsiderable. A chronic ulcer left in situ, in healing, produced stricture of the pylorus, "hour-glass" stomach, stenosis of the cardiac end, or became malignant in perhaps 40 per cent. of cases—the figure given by Mr. Sherren. He recommended cauterisation by the Balfour method in small, easily accessible ulcers, with the addition of gastro-enterostomy, and a sleeve resection in cases where there was a fair amount of healthy stomach both proximal and distal to the ulcer. A union between the two segments gave good functional results. An indurated chronic ulcer at the pyloric end was treated by closure of the duodenum, partial gastrectomy, and anastomosis in front of the colon between the jejunum and the proximate segment. In one case, in order to get above a chronic ulcer in a woman aged 60, he was obliged to remove the entire stomach. He showed seven specimens of chronic ulcer and malignant disease of the stomach removed recently by partial gastrectomy. He had operated upon one case of gastro-colic jejunal fistula. Small ulcers with a free mobile stomach could be safely treated by gastro-enterostomy.

Mr. A. B. MITCHELL said that Mr. Sherren's wise paper almost disarmed criticism. One thing he had said

with which the speaker could not agree, was that the operation of gastro-jejunostomy was a cure for gastric ulcer. Mr. Mitchell was of opinion that in many cases of simple non-malignant ulcer gastro-jejunostomy would not effect a cure. The operation for gastric ulcer was a serious one. He would never put the operative risk in disease of stomach under 3 per cent. Even the simplest operation was sometimes borne badly by the patient. The idea of a perfect stomach was, he thought, one that was freely movable, and this was a condition which had got to be secured at operation. It was remarkable how little stomach a person required to live and to be healthy. The question of heredity was an interesting one. Mr. Mitchell quoted cases of family incidence. He believed that the ideal place for gastro-jejunostomy was the pre-pyloric pouch, as he thought the higher up it was done the less likely the patient was to have comfort afterwards. Sometimes a patient would remain well for perhaps ten years after operation and then would come back complaining of stomach symptoms. In these cases he always suspected peptic ulcers, and though after medical treatment the patients got practically well, they never had much comfort and generally came back for another operation. The so-called silent gastric ulcer occurred in patients who came into hospital with acute perforation, the result of a hard ulcer which must have been present for at least three years, and yet the patients said they had never had any symptoms whatsoever, neither indigestion, nor pain, nor anything else.

Mr. SETON PRINGLE confined his remarks to the discussion of the various operative measures for hour-glass stomach. He referred briefly to the diagnosis of the condition, laying stress on the importance of X ray examination. He exhibited slides illustrating the different methods he had employed in this condition, with, in many cases, X rays of post-operative results. In conclusion, he stated his belief that partial gastrectomy, where possible, was the most satisfactory operation, but that where this was not feasible a posterior gastro-enterostomy into the upper sac was the best procedure. Where the distal sac was large, or obstruction of the pylorus or duodenum also existed, he advised that a second stoma be provided from the distal sac into the same or another loop of jejunum. In cases of difficulty he had no hesitation in performing an anterior gastro-enterostomy, with or without an entero-anastomosis. He classed as unsatisfactory all direct attacks on the constriction. He regarded as essential the excision of an active ulcer should such be found at the operation.

Mr. R. C. B. MAUNSELL was absolutely in accord with most of what Mr. Sherren had said, and he was glad to hear him re-state that gastro-enterostomy would cure most gastric ulcers and all duodenal ulcers. This was a fact which was known and believed some years ago, but which lately had become unfashionable. He personally only performed gastrectomy in cases of malignant disease, and he thought that ten years hence this operation would not be known at all. Gastrectomy performed in cases of ulcers might justly be called over-operating.

TUBERCULOSIS SOCIETY.—An ordinary meeting of this society will be held to-day (Friday), at 8 P.M., at the Margaret-street Hospital, Margaret-street, W., when Dr. Alex Sandison and Dr. Basil Price will read papers on the Tuberculosis Work of the Ministry of Pensions, Administrative and Clinical.

The annual provincial meeting will be held at Cambridge on April 10th, 11th, and 12th, when the following lectures will be delivered:—April 10th: Dr. Louis Cobbett, A Comparison of Tuberculosis in Man and Animals; and Dr. E. Ward, Experiences with Diaplyte Vaccines. 11th: Dr. R. C. Matson, of the National Tuberculosis Association of America, will speak on Tuberculosis Work in America, Dr. Stanley Griffith on Lupus, and Mr. G. R. Girdlestone on the Present Day Treatment of Bone and Joint Tuberculosis. On the 12th a visit will be paid to the Papworth Colony by invitation of Dr. P. C. Varrier-Jones, the medical director. Particulars regarding travelling arrangements and accommodation may be had from Dr. F. J. C. Blackmore, hon. secretary, 38, Herbert-road, Plumstead, S.E. 18.

Reviews and Notices of Books.

PSYCHIATRY.

Occupation versus Restraint. By L. VERNON BRIGGS, M.D. Boston, Mass.: Wright and Potter. 1923. With 10 illustrations. Pp. 205.

THIS book is a record of its author's efforts to improve the conditions of asylum treatment in Massachusetts. It has to be remembered that the lunacy laws of the States composing the U.S.A. exhibit wide variations, and the reforms in which Dr. Briggs was the leading protagonist were already accomplished and accepted as a matter of fact in the State of New York before his work began. Apparently the laws of Massachusetts admitted of various abuses; in State asylums the attendants were generally of an unsuitable type, and not infrequently brutal in their treatment of patients; mechanical restraint was commonly practised and insufficiently recorded, and occupation therapy was neglected. Numerous private asylums existed, innocent of any adequate State control, and conducted principally for financial gain; in these various abuses were alleged. Owing almost entirely to the energies of the author, two Bills were passed in the year 1911 by the Senate of Massachusetts, the main effects of which were severely to limit the uses of restraint, to institute the proper selection and instruction of attendants, and to introduce occupational treatment. This record of the years spent in attaining these ends reads almost like a personal diary; much correspondence, some of which appears trivial, is quoted verbatim, and a good deal of space is devoted to an aspect of the work which must remain a source of regret to everyone concerned—namely, the personal antagonisms among interested members of the medical profession in Boston which were occasioned by it. The history of this legislation, typical as it is of the advances which mental treatment has made, and is making, throughout the civilised world, is of the first interest, and Dr. Briggs's exposition of it leaves nothing to be desired in clarity, detail, and enthusiasm, but it seems unfortunate that after the lapse of over ten years the differences with his colleagues which these efforts entailed should still receive public advertisement and emphasis.

Record of events subsequent to 1911 is, unfortunately, scanty; more space may perhaps be devoted in a future edition to the effects of the changes made in that year and to the position at the present day. It is always difficult to visualise the conditions of treatment of the insane in the United States, since geographical variations both in the law and in its application still appear to be considerable.

Addresses to Mental Nurses. A Series of 15 Lectures delivered to the Nursing Staff of The Retreat, York, by Various Authorities. Edited and arranged by BEDFORD PIERCE, M.D., F.R.C.P. London: Baillière, Tindall and Cox. 1924. Pp. 288. 7*s.* 6*d.*

DURING the past 22 years it has been customary at the York Retreat each year to invite a distinguished alienist to deliver an address to the nursing staff. Dr. Bedford Pierce, until recently medical superintendent of The Retreat, has published 15 of these addresses in book form, each being preceded by a short account of its author, a feature which adds greatly to the interest of the volume. Although broadly concerned with the practice of nursing, the subjects chosen vary considerably; several are really lay sermons on the higher duties of nurses to the insane, and on the motives and character which must underlie their work. In some cases the subjects are more technical—for example, the late Dr. James Middlemass on night nursing, and Dr. Henry Devine on occupation therapy. A few deal with what may be called the philosophy of mental alienation, and not a few vital questions of ethics receive considerat on. One of these is summed up in a quotation from the late Dr.

Charles Mercier: "I can conceive of circumstances in which it might be right to deceive a sane person, but I can think of none which justify the deception of an insane person." Perhaps the wittiest in a company not by any means devoid of humour is the late Sir George Savage, in an address on the Private Nursing of Mental Patients; many of his anecdotes are worthy of an accessible pigeon-hole in the reader's memory.

The publication of these addresses may be welcomed not merely on the score of their scientific and literary merit, but because the book fulfils two purposes which are served by no other. As a medium for conveying some idea of asylum work, its difficulties, and the spirit in which they are faced, it is capable of improving public understanding of this work, a function of which no other book in existence is capable; if it should have the effect of inducing educated women to enter the mental nursing service it will have served another valuable purpose. For mental nurses themselves it provides a stimulus and an interest which are perforce lacking in their text-books, and it is very much to be hoped that mental hospitals throughout the country will see that copies are available for such of their staff as are unable to buy it. Just as the education of a medical student may be considered incomplete until he has read such classics as "Confessio Medici," and Lauder Brunton's lectures on the Action of Medicines, so should this book in future years be regarded as essential to the higher education of the mental nurse.

RADIOGRAPHY AND RADIOTHERAPEUTICS.

Vol. I., Radiography. Fourth edition. By ROBERT KNOX, M.D., C.M. Edin., Hon. Radiographer, King's College Hospital, London. London: A. and C. Black. 1923. Pp. 448. 40*s*.

Dr. Knox's work has come to be recognised as one of the best books on radiology published in this country, and has established the author's reputation abroad. This first volume of the fourth edition is occupied entirely with radio-diagnosis, and in the first part dealing with electrical supplies, apparatus, and the equipment of X ray departments there is little notable change from earlier editions. The publisher's note tells us that advantage has been taken of the opportunity to revise carefully the text and to add the results of considerable advance in the technique for the examination of the liver, gall-bladder, and urinary tract; but in view of the more elaborate volumes dealing with the chest and the gastro-intestinal tract which the author has in preparation, it was decided to leave these last-named sections practically unchanged.

This paragraph shows at once the strength and weakness of this edition. The strength is manifested in the excellent sections on X ray examinations for diseases of the gall-bladder and kidney which give all that is good and latest in the investigation of these conditions and pyelography. The anatomical considerations are clear and well put, and particular attention must be drawn to the very practical and illuminating Appendix I.—viz., "Observations on Cases Illustrating the Differential Diagnosis in Renal and Gall-bladder Work." It seems unfortunate, however, that for whatever reason the sections on the thorax and gastro-intestinal tract should not have been brought so fully up to date. Cardiospasm, a phenomenon of increasing interest, still receives scant notice, while, although Carelli's method of perirenal inflation is dealt with at some length, the reader looks in vain for material on which to form an opinion regarding the value of artificial pneumoperitoneum as an aid to X ray diagnosis. In the section on thorax no great stress is laid on the use of stereoscopy in the examination of chest conditions, especially in the question of the diagnosis of early tuberculosis, where it may be of the greatest value. Nor are there any references to the examination of chests after the production of artificial pneumothorax, a proceeding of very definite diagnostic value, bringing the radiologist into touch with the general physician.

The chapters on injuries to bones and joints have been rearranged and enriched by many additional illustrations. In fact, in spite of the loss of definition which is inevitable in the reproduction of X ray negatives, the prints are clear and form a notable feature of every part of the book. Besides the appendix mentioned above, there are notices of the Protection of X-ray and Radium Workers, and a brief description of the working of a Lilienfeld tube, while the Potter-Bucky diaphragm is still kept in the appendix section and no references are made to attempted modifications. The subject of radiography in midwifery is not discussed, and is perhaps the biggest complete omission. But the author has had to use much judgment in what things deliberately to leave out. At the present time there is no better work than Dr. Knox's on its subjects.

OPHTHALMOLOGY.

Lehrbuch der Augenheilkunde. By Dr. PAUL RÖMER, Director of the University Eye Clinic at Bonn. Fourth revised edition. With 306 illustrations in the text and 32 coloured plates. Berlin and Vienna: Urban and Schwarzenberg. 1923. Pp. 500. 15 Standard Marks.

THE third edition of this text-book was reviewed in these columns some four years ago and the revision to which the present edition has been subjected has not materially altered it. The illustrations, and especially the coloured ones, are remarkably good, a fact which makes the work valuable to the non-German student. The style is concise and there is no superfluous matter. Indeed, in a work on this scale the student could wish for a fuller treatment of some important subjects such as glaucoma. The book does not profess to be a guide to ophthalmic operations.

THE INSULIN TREATMENT OF DIABETES MELLITUS.

By P. J. CAMMIDGE, M.D. Lond., D.P.H. Camb. Edinburgh: E. and S. Livingstone. 1924. Pp. 172. 6*s*.

THE book opens with an account of the previous attempts which have been made to find the internal secretion of the pancreas, and goes on to give a short description of the circumstances which led Banting to discover insulin. An account is then given of the early clinical results obtained by the Toronto workers. The exact meaning of the term diabetes mellitus and the different conditions which are included under this name are considered, and Dr. Cammidge sets out briefly the different types which he has distinguished. [This work has been dealt with at length in the author's book entitled "New Views on Diabetes Mellitus," which was recently reviewed in these columns.] The indications for the use of insulin are then described, and an account is given of Kellog's table for drawing up a diet for a patient. The ideals of treatment, no sugar in the urine and a normal blood-sugar, are then discussed.

The actual method which the author uses is a most formidable one, as it entails the carrying out of a very large number of investigations in order to place the type of the disease, and this can only be done in the laboratory. The patient is given a standard diet which contains a large amount of carbohydrate, often 80 g., so as to determine the severity of the disease. A test breakfast is given, and the blood-sugar investigated at short intervals after it. On these findings it is decided whether the type is suitable for treatment with insulin. So far about 50 per cent. of the patients examined have not been deemed suitable, as the glycosuria could be controlled by dietetic restrictions. Details of these cases are given, and also of many others in which insulin was used with much benefit to the patient. The amounts of carbohydrate which Dr. Cammidge aims at giving are much larger than

are used by other workers, 95 g. in one case being used with 40 units of insulin. Renal glycosuria and its dangers with regard to insulin are touched on, and an account is given of the symptoms of hypoglycæmia. One patient, who was eating 90 g. of carbohydrate, having had 40 units of insulin, was taken ill because he omitted to eat the usual amount of carbohydrate after his morning dose of insulin. He quickly recovered from the state of hypoglycæmia when sugar was given. The treatment of coma is discussed and also the ill-effects of infections. The point is made several times that insulin is not a cure, and that the statements in the lay press have had an unfortunate effect on many patients who think that they can have insulin and eat what they like.

The book is not very easy to read, and the account of the treatment with insulin is somewhat overloaded with details of the diagnosis of the condition, but it contains much interesting matter, is well printed, has a good index, and is moderate in price. It conveys valuable and practical lessons.

THE CHEMICAL BASIS OF GROWTH AND SENESCENCE. By T. BRAILSFORD ROBERTSON, Ph.D., D.Sc., Professor of Physiology and Bio-chemistry, University of Adelaide, South Australia. London: J. B. Lippincott Co. 1923. Pp. 389. 12*s.* 6*d.*

THE appearance of a monograph on the chemical basis of growth will be welcomed by all students of experimental biology whose lot it is to study that "transient force which, by an impulse, seizes flesh and grows to man."

In an introductory chapter the author stresses the similarity between the growth curves of animals and plants, and the curves of autocatalysed monomolecular reactions. It is realised, however, that the process of protoplasmic synthesis is actually an exceedingly complex one, involving multitudinous parallel, successive and independent reactions. To show that a simple formula, such as that which characterises the progress of a monomolecular autocatalysed reaction can be applied to a complexity of events, it is necessary to invoke the idea of a "master reaction." The slowest reaction in a series of chemical reactions is looked upon as governing the time relations of the whole, much in the same way as in a factory the slowest of the diverse operations determines the daily output of the finished product. In the higher metazoa, at any rate, it is suggested that the forward reaction, governing protoplasmic synthesis, is actually polymolecular, though the reverse reaction of protoplasmic breakdown is probably monomolecular. In succeeding chapters the growth curves of man, animals, plants, and unicellular organisms are considered in relation to the foregoing theory. "Allelocatalysis" is dealt with at some length, more especially in relation to the development of Enchelys. It is of interest to note that more recent work has failed to confirm the necessity for the animal to develop a definite concentration of "X substance" before division can take place. Although growth-promoting substances undoubtedly exist it is doubtful whether their action is as simple as the author suggests.

The substrates of growth—that is to say, the raw materials of protoplasmic synthesis, inorganic salts, amino-acids, and accessory food factors—are next considered; after which senescence and the retarding influences of growth receive attention. The conclusion is reached that senescence is the necessary outcome of differentiation. This is followed by a brief but highly speculative consideration of cancer, and an equally speculative chapter dealing with the relation of lecithin, cholesterol, and "tethelin" to growth.

As an example of the author's conception of growth, the law which regulates the growth of the cells of a higher animal under ordinary conditions, may be given in his own words. "The accumulated autocatalyst of nuclear synthesis, stored up in the nuclei and prevented from escaping at the moment of nuclear division by the abundance already present in the nutrient medium, finally accelerates the reverse reaction of nuclear synthesis to so great an extent that the velocity of the reverse reaction becomes equal to that of the forward reaction, before the critical nuclear ratio which is requisite for cell division is attained. Further cell multiplication is thus inhibited and stasis is imposed."

The origin of cancer, as the result of repeated repair of injured tissue, is interpreted as "a process of selective breeding whereby the cells of the lowest nuclear ratios" (Hertwig's Kern-Plasma relation) "are favoured and enabled to propagate. Should the inherited variability of the cells in the locality enable at length the appearance of a type of cell so physiologically differentiated from its competitors as to be able to multiply freely at the prevailing nutrient level and in the presence of the prevailing accumulations of autocatalyst, then an outburst of reproductive activity must inevitably ensue and the successful type of cell will inaugurate, if it is sufficiently differentiated, a malignant tumour." This sounds more impressive than illuminating. A bibliography of some of the more important literature on the subject of growth is appended.

The treatment of the subject varies from applied mathematics to reckless speculation, but the book on the whole is of considerable interest as an individual attempt to interpret the various aspects of the growth problem.

TOXICOLOGIE.

Fourth edition. By FONZES-DIACON, Docteur ès Sciences, Agrégé de Chimie et de Toxicologie, Professeur de Chimie Minérale à la Faculté de Pharmacie de Montpellier, &c. Paris: A. Maloine et Fils. 1924. Pp. 452.

THIS work, now in its fourth edition, is a useful practical handbook on toxicology. Of moderate dimensions, it does not pretend to deal with the subject exhaustively, but there are few substances likely to produce poisonous symptoms which do not receive attention. The writer has evidently had wide experience in the isolation and detection of poisons, and has described admirably the analytical details necessary. His methods are sound and the processes readily followed. The descriptions of the symptomatology, post-mortem findings, and the treatment are the least satisfactory parts of the book. There is a great difference between an account of the symptoms and a graphic picture of a patient suffering from a particular poison, and the descriptions here given are, unfortunately, of the former type. The treatment is mainly limited to the enumeration of correct chemical antidotes, little attention being paid to the all-important, general treatment of the patient. The index is poor, the page number of the principal reference only being given.

JOURNALS.

JOURNAL OF ANATOMY. Vol. LVIII. Part DD. January, 1924. Cambridge University Press. Pp. 91. 10*s.*—A number mainly composed of short papers. Dr. H. H. Woollard gives an account of his results in vital staining of the leptomeninges, his experiments being planned to avoid that toxicity which certainly complicated the results of some of Goldmann's experiments.—Prof. J. T. Wilson describes how he applies the Spalteholz clearing method to the study of thick serial sections of embryos. Those who had the opportunity of seeing the striking specimens shown at Cambridge last summer by him will be glad to have an account of their preparation. Prof. Wilson is not yet satisfied with the permanency of his staining.—Mrs. Katharine M. Watson has an interesting and important paper on the development of heart and blood-vessels of the cat.—Prof. F. H. Edgeworth gives a useful account of the masticatory, intermandibular, and hyoid muscles of *Orycteropus capensis*.—An excessively rare variety of abnormal atlas is described by Dr. R. H. Hunter. In this the

original body (odontoid process) remains attached to the atlas.—Prof. Gordon Harrower gives some short remarks on embalming in the tropics.—An account of rudimentary otocephaly in a human fœtus is given by Prof. J. A. Pires de Lima. This variety of monstrosity is not very rare among lambs and kids.—Prof. N. Kulchitsky follows with an important paper embodying his observations on nerve-endings in muscles; he has worked particularly on the muscles of Python, in which he shows the existence of two types of motor-nerve terminations, and deals with many details of structure.—Dr. R. J. Gladstone has a suggestive note on the post-natal growth of the kidney, thyroid gland, and liver, considering these from the point of view of enlargement of the unit structure (hypertrophy) or increase in number of such structures (hyperplasia).—The last contribution is a short account, by Mr. W. W. Wagstaffe, of a rare duodenal anomaly.

British Journal of Anæsthesia. January, 1924.—The January number of this quarterly starts with an attractive little historical article on John Snow by Dudley Buxton.—J. T. Gwathmey follows with an account of laboratory and clinical experiments with ethylene and other hydrocarbon gases. From this it appears that ethylene has its uses as an anæsthetic, but not as one which is to be relied on unaided to produce satisfactory anæsthesia. Its analgesic more than its anæsthetic properties appear to have impressed themselves on the investigator. Another article deals with endo-tracheal administration of gas and oxygen with ethanesal and chloroform, a method warmly extolled by Langton Hewer, who gives details of technique and records admirable results. Warm ether vapour, pulmonary after-effects, reciprocity between surgeon and anæsthetist, and other problems form the subject matter of further contributions. The useful current bibliography is continued, and if our contemporary can hold its present form it should become firmly established.

Indian Journal of Medical Research. January, 1924.—W. G. Liston and M. B. Soparkar write upon bovine tuberculosis in India with special reference to an outbreak amongst the animals in the Bombay Zoological Gardens and the types of tubercle bacilli isolated.—N. L. Banerji has a paper on the influence of hydrogen-ion concentration on the dose of alum employed in the clarification of natural waters.—L. E. Napier describes the reaction of the blood in kala-azar.—R. Knowles and B. M. Das Gupta contribute a note upon a flagellate protozoon found in the saliva.—R. McCarrison continues his series of papers on the pathogenesis of deficiency disease.—A. J. H. Russell, A. Ayyar, and Urhaya make some epidemiological observations on an epidemic of relapsing fever in Madras Presidency.—J. A. Sinton provides a valuable contribution to our knowledge of the Indian species of phlebotomus.—U. N. Bramachari, S. C. Chaudhury, J. Das, and P. B. Sen write upon the chemotherapy of antimonial compounds.—P. J. Barraud continues his revision of the culicine mosquitoes of India.—N. H. Fairley and W. G. Liston commence a well-illustrated account of the pathology of dracontiasis.—W. S. Patton writes upon the occurrence of *Hypoderma lineatum* in the Punjab.—H. E. Shortt and C. S. Swaminath have succeeded in infecting a mouse by means of bed-bugs fed on the peripheral blood of a case of kala-azar.

Glasgow Eye Infirmary.—Dr. John Edwards presided at the hundredth annual meeting, recently held, of the Glasgow Eye Infirmary. In the course of his speech he traced the history of the infirmary from its inception in 1824 up to the present day, when it occupies a commodious building in the west end of Glasgow. Dr. W. Gillies intimated that there was a credit balance of £18,948 for the present year, as a result of a donation of £20,000 from Mr. John Ross's trust. Indoor patients had each cost on the average £6, while the expenditure on outdoor patients had averaged 1s. per patient. The centenary celebration will take place in June next.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XI.—MEDICAL PARTNERSHIPS.

By James Neal, M.R.C.S. Eng.,
General Secretary of the Medical Defence Union.

More than most men the family physician feels the tragedy of isolation.—*William Osler.*

In these days of specialisation it is no longer easy for an individual medical practitioner to cope single-handed with the various aspects of disease met with in what is still called general practice. Twenty or thirty years ago medical practitioners were more generally content to practise independently.

Advantages and Drawbacks.

It is now realised that many advantages can be gained by coöperation, and it is not at all unusual to find multiple partnerships in which the different members of the firm specialise in various departments of medical work to the benefit of all concerned. A firm of medical partners which includes an operating surgeon, an obstetrician, an X ray operator, an oculist, and possibly an ear and throat specialist, is able to cope with almost any conceivable variety of ailment which may be met with in practice, without any necessity for calling in outside help, and therefore occupies a very strong position as compared with an isolated individual practitioner who must necessarily refer his patients to an independent specialist in many circumstances. Moreover, since the introduction of the Insurance Act, it has become more difficult for a young medical practitioner to acquire a practice by the simple process of putting up his plate. It is therefore not surprising to find that medical partnerships are becoming more numerous.

The advantages are obvious. Responsibility can be shared; the capital value of the practice can be maintained better; outside competition can be more easily met; holidays can be arranged without loss; and team-work can be carried on with all its benefits. It has to be admitted that a man who enters a medical partnership must be prepared to sacrifice a certain amount of independence; but the advantages to be gained are so great that there is no doubt the arrangement would become far more general, except for the unfortunate differences that not infrequently arise.

Experience in adjudicating in partnership disputes has convinced me that many of the difficulties peculiar to medical partnerships can be obviated. No medical partnership can be carried on satisfactorily unless there is mutual goodwill between the partners. Consequently, anything likely to become a cause of disagreement must be avoided studiously from the outset. Jealousy is perhaps the rock on which a medical partnership is most likely to be wrecked, and should be carefully guarded against. Mutual trust and loyalty are essential, and each partner should realise that he must play the game in the public-school spirit.

Nature of the Contract.

If a partnership is entered upon for a short fixed period, at the expiration of which both partners may continue practising in the place, not only is the saleable value of either partner's share negligible, but there is a distinct inducement to each partner to compete with the other for a hold on the patients. It is therefore preferable that the duration of a medical partnership should be for the joint lives of the partners, with provision for either partner to dispose of his share after giving the requisite notice; except in those cases where a brief partnership is arranged deliberately with a view to the acquisition by the junior partner, after a specified period, of the whole practice.

In all partnerships with a view to succession, it is desirable that the date of the retirement of the senior partner should be definitely stated in the agreement, and also the terms upon which his share in the partnership shall be acquired by his successor. An ordinary partnership should be terminable by either partner giving due notice at any time after the first few years; so that if either partner finds the partnership unsatisfactory it is possible for him to dispose of his share and thus withdraw from the partnership. It should, however, be an essential proviso that the retiring partner may not continue to practise in the district.

A medical practitioner who enters into partnership with one or more other medical practitioners necessarily finds himself bound by the ordinary obligations imposed upon any persons "carrying on a business in common with a view to profit." But a partnership between two or more medical practitioners differs in some respects from a partnership between persons engaged in any other profession or trade. Medical partners hold little joint stock; their principal partnership asset is the goodwill of the practice. Consequently, the profits of the partnership are not derived from the share which each partner has in the partnership assets, but from the professional work of each partner.

From the strictly legal point of view a partnership may be created by a verbal contract, or may even be inferred either from the fact that the profits of a joint business are shared, or that the parties allow their names to appear in such a way as to imply that they are carrying on the practice as partners. In all medical partnerships it is essential that a formal agreement of partnership should be entered into and signed before any act of partnership is performed. Too often as soon as a medical partnership is decided upon, the work of the partnership is allowed to commence before many necessary details are settled. I have known months, and, in some cases, several years, elapse before the actual legal agreement was even drafted. If any disagreement should then arise, the position may easily become extremely complicated, and disaster may result.

Drawing Up the Agreement.

The agreement of partnership is a most important document. It should invariably be prepared by a solicitor who is experienced in the peculiar difficulties which are likely to arise in connexion with medical partnerships, and who is therefore able in a great measure to guard against them. The slightest ambiguity in the wording of a clause in the partnership agreement frequently leads to serious differences between the partners, and may even make the continuance of the partnership impossible.

All partnership agreements should define:—

1. The duration of the partnership.
2. The terms on which the share of the incoming partner is to be acquired, and the terms on which his share may be increased from time to time.
3. The mutual rights and duties of the partners.
4. The property of the partnership.
5. The expenses to be met by the partnership.
6. The fees to be charged.
7. The terms of dissolution in varying contingencies, including the restrictions to be imposed on a retiring or outgoing partner.
8. The procedure to be adopted in the event of any disputes between the partners.

Other matters properly to be included are provision for the keeping and auditing of the accounts, for periodic division of profits, for holidays, and for dealing with prolonged absence or incapacity of either partner. Whenever a medical practitioner contemplates entering into a partnership, a careful investigation of the books of the practice should be made by a competent accountant, experienced in medical book-keeping. This is as essential as when a practice is to be bought outright, but is a precaution too frequently dispensed with. It is also well to make sure that a prospective partner is a duly registered medical practitioner. There are several cases on record where an unqualified person has successfully represented himself to be registered, and has been taken into partnership without any suspicion being aroused or inquiries made.

A partnership agreement may always be varied by the consent of all the partners. Many difficulties and disputes would be avoided if any departure from the strict letter of the partnership agreement made with the consent of all the partners were recorded in writing, as frequently such consent may be inferred from the circumstances of the case. It has been held in some instances that the constant usage of partners is sufficient to supersede the articles of partnership. This must not, however, be taken to mean that an occasional failure to comply with the strict letter of the agreement invalidates the written provisions.

Reciprocal Responsibility.

Every partner is entitled to take his share in the management of the business of the partnership, and is under an obligation to devote himself diligently to the work of the practice. Special importance attaches in the case of a medical partnership to the following clause in the Partnership Act, 1890:—

§ 10. Where, by any wrongful act or omission of any partner acting in the ordinary course of the business of the firm, or with the authority of his co-partners, loss or injury is caused to any person not being a partner in the firm, or any penalty is incurred, the firm is liable therefor to the same extent as the partner so acting, or omitting to act.

This means that each partner in a medical firm will be responsible for any other partner's negligence or malpraxis. It is consequently usual to include in a partnership agreement a clause whereby each partner is required to make good any loss occasioned to the firm by negligence or misconduct on his part. The most desirable arrangement is to stipulate that all the partners should be and remain during the continuance of the partnership members of one of the medical defence societies, and preferably that all should belong to the same society.

It is usual for each partner to provide his own surgical instruments, and also to provide his own means of locomotion. But special arrangements must be made in exceptional circumstances.

Division of Labour.

The division of the work among medical partners is a matter of arrangement, but the general principles should be decided beforehand, and embodied in the agreement. When a younger man is taken into partnership by an established practitioner who wishes to be relieved of some of his work, it is only right that the senior partner should decide largely which cases should be seen by the junior. This does not mean that the junior should be treated as an assistant, and many promising partnerships have been ruined by unfair treatment in this respect. The junior must reasonably expect to be given the less important work for a time, but his rights as a partner must not be infringed. For instance, it would be unreasonable for the senior partner to expect his junior partner to take all night calls and midwifery, unless it was a special arrangement agreed to before the partnership was entered into, in which case it should be embodied in the Articles.

The position is different when the partnership has been arranged with a view to the succession of the junior within a comparatively short period. His effective introduction is essential to the proper transfer of the goodwill, and must not be unduly delayed. A judicious arrangement of the work with due regard to the susceptibilities of the patients should be possible, and must be insisted upon. When there are more than two partners, any difference arising as to ordinary matters connected with the partnership business may be decided by a majority of the partners.

Assistance with a View to Partnership.

No one should consent to act as an assistant with a view to partnership on a mere verbal assurance that he will eventually be admitted into partnership. Too

often it is found that the intentions of the principal change, and that after repeated delays some more or less imaginary reason is advanced for not carrying out the original intention. When a preliminary service as an assistant with a view to partnership is suggested, it is well to insist that a definite agreement for partnership to commence on a future date specified in the agreement shall be entered into and signed by both parties. To guard against incompatibility, liberty should be given to either party to cancel the agreement within a specified period, not exceeding six months, in which case the proposed partnership would be nullified.

CERTIFICATION IN INSURANCE PRACTICE.

Dr. J. Hedley Marsh, of Macclesfield, comments as follows on the article by Mr. L. Shoeten Sack which appeared in THE LANCET of March 1st, p. 450:—

"Mr. Shoeten Sack states that where a doctor neglects to grant an intermediate certificate within 24 hours of seeing the patient he should not use the new voluntary certificate, but should use the 'regular form of certificate.' If by regular form of certificate he means form Med. 40 revised, he is, I believe, in error. The doctor should give one of his own private certificates or write on a plain piece of paper. Rule 8 is quite explicit, and the Commissioners' ruling in a recent case here in Cheshire forbids the use of the official form Med. 40, except as expressly laid down. The whole question of certification is a nightmare to the conscientious practitioner. It now requires a barrister-at-law to interpret its verbiage, and even with his help a wrong construction may be placed on the official jargon."

Mr. Shoeten Sack replies: "Rule 8, considered by itself, might suggest this interpretation. Rule 2, however, limits the use of the prescribed forms of certificate by providing that these forms 'shall not be used on any occasion on which the practitioner is not required by these Rules to give a certificate.' This clearly prohibits their use where the insured person is himself responsible for a delay in the issue, for in such a case the doctor is not 'required' to give a certificate but may use the voluntary or a private certificate as an act of grace. Article 2 does not, however, seem to exclude the issue of a regular certificate where the patient has made due request, and the doctor has neglected to give the certificate within 24 hours; for then, in spite of his dilatoriness, the doctor is still 'required to give a certificate.' Rule 8 merely defines the doctor's obligation as to the time when the certificate is to be issued. If, after due request, the doctor neglects to issue the certificate within 24 hours of the examination, he admittedly commits a breach of this rule, but the insured person still remains entitled to receive the regular certificate for which he asked at the proper time. If it were otherwise, what would become of the requirements in Rules 3, 4, and 5 that the doctor *shall*, if desired by the insured person, issue a first or intermediate certificate? The breach by the doctor of Rule 8 cannot be held to render the other rules of no effect.

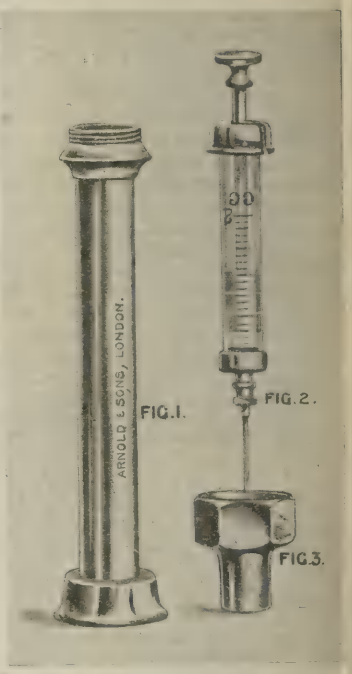
"In the memorandum, Form G.P. 37, which was sent to insurance doctors when notice was given of the altered terms of service under the Medical Benefit Regulations, 1924, the Minister of Health thus explains the point (para. 10(*c*)): 'It should be specially noted that they [the voluntary certificates] cannot properly be used in cases in which the practitioner was himself at fault in not issuing within the required time a certificate which it was his duty to issue. In cases where the patient was not at fault but the doctor has omitted to give or send a certificate within the time specified in Rule 8, an ordinary official certificate should be issued, showing the date of examination and the date of signing.' The 'ordinary official certificate' in this passage means any of the prescribed forms of certificate other than the voluntary certificate, and therefore, of course, includes Form Med. 40 revised.

"The Cheshire case which Dr. Marsh quotes was presumably either a case which arose before the introduction of the voluntary certificate, or it referred to the issue of Form Med. 40 where the insured person himself was at fault through having neglected to ask for a certificate at the proper time."

New Inventions.

A NEW INSULIN SYRINGE.

THE repeated injection of insulin frequently causes inflammatory reaction and a hardening of the tissues. With the ordinary Record syringe and needle this causes a marked resistance to the injection of the fluid, and in many cases there is a loss of from 3 to 4 minims of insulin past the plunger of the syringe. When to this is added the necessity of continued sterilisation, repeated daily injections may become very irksome. I have had devised a syringe and holder to overcome these difficulties. The syringe is a 2 c.cm. Record armed with a No. 19 or 17 needle. The plunger is grooved to hold two well-fitting spring piston rings, the gaps in which are so adjusted as not to be in line. This syringe (Fig. 2) will hold a very high degree of compression, and will not leak past the plunger. The container of the syringe is a metal cylinder with an alcohol-tight screw cap. The syringe is kept in absolute alcohol within the container and is always sterile. The fitting of the cap is so arranged that it is not necessary to have any leather or rubber washers, and yet is perfectly spirit-tight. The metal container (Fig. 1) has a wide, flat, heavy base and will stand upright. The screw cap (Fig. 3) has also a flat top, carries a spring which holds the syringe immobile in the container, and is sufficiently deep to hold a drachm of alcohol. The syringe is admirably adapted for the injection of any fluid against great resistance. The idea has been applied to a series of syringes of varying sizes for different uses. In my hands their use has been uniformly pleasing.



The syringes are made by Messrs. Arnold and Sons (John Bell and Croyden, Ltd.), 50–52, Wigmore-street, London, W. 1.

Welbeck-street, W. TILSON DINNICK.

GROCERS' COMPANY'S RESEARCH SCHOLARSHIPS.—With the object of encouraging original research in sanitary science, the Grocers' Company offer three scholarships each of £300 a year, with an allowance to meet the cost of apparatus and other expenses in connexion with the work. The scholarships are tenable for one year, but renewable for a second or third year, subject to the conditions of the scheme under which they are established. The next election will take place in May, 1924, one scholarship being now vacant. Applications must be sent in before April 1st to the clerk of the Grocers' Company, Grocers' Hall, London, E.C. 2, from whom a form of application and further information may be obtained.

THE LANCET.

LONDON: SATURDAY, MARCH 15, 1924.

THE SYSTEMIC EFFECTS OF RADIATION.

FOR a long time after the destructive effects of X rays and radium on various kinds of pathological cells had been ascertained, attention was concentrated upon this action rather than upon the physiological effects of radiation on the tissues in general, and it is only within the last three or four years that the dangers attending the use of gamma rays are being fully revealed. Superficial damage to the skin caused by the softer types of X rays, and resulting in dermatitis or something worse, was the first to attract general notice; more recently the damage done to the deeper structures including the blood-forming organs by the more penetrating types of X rays and the gamma rays of radio-active substances has been observed. Taking the skin as a type of tissue moderately vulnerable to radiation, we can now classify tissues roughly into those of greater and lesser vulnerability—on the resistant side, muscle and nerve tissue; on the susceptible side, blood-cells and germinal tissue; and to the latter must now be added the cells lining the alimentary canal. In a recent article [1] allusion was made to some valuable American studies on X ray intoxication with special bearing on radiation of the abdomen. Experiments on dogs showed that a dose of X rays which, directed over the thorax, gave no clinical evidence of intoxication, ensured the death of the animal on the fourth day if given over the abdomen. Going further, it was found that in dogs the secretory crypt of epithelium of the small intestine was the first to undergo autolysis. These experiments gave no support to the belief that X ray nephritis might be produced by hard Rontgen rays, since the epithelium of the kidney was found to be much more resistant than the epithelium of the small intestine.

We publish this week a study of the metabolic changes associated with X ray and radium treatment undertaken by Dr. E. C. DODDS and Dr. J. H. DOUGLAS WEBSTER, who recount the results of a piece of laborious work which was completed in August of last year. The machinery of two scientific departments at the Middlesex Hospital was set going to determine the essential biochemical changes involved in radiation toxæmia, or X ray sickness as it has graphically been called. The aim of the research was to determine, by a study of basal metabolism, what are the characteristic changes in radiation toxæmia, in order to bring these changes into relation with other comparatively well-known toxæmias such as those occurring during anæsthesia, in the course of diabetes, as a result of fevers, migraine, uræmia, and the like. A primary difficulty in this investigation, which was carried out entirely upon the human subject, was to appraise correctly the three factors necessarily complicating the results—namely, the disease in question, the effect of treatment on the disease, and finally the effect of the rays on the patient's metabolism. Four clinical groups of disease were investigated, the patients being in bed and maintained on constant diet, while the urine collected in 24-hour specimens was completely analysed for urea, uric acid, ammonia, acidity, total nitrogen, ammonia coefficient, phosphates, chlorides, creatinin, and diastase. The results of all these clinical findings coincided in a remarkable degree with those obtained experimentally in animals by the American observers. The changes in metabolism, closely similar whether X or gamma rays were employed, were found to vary essentially with the site radiated. Radiation of head, thorax, or limbs produced no appreciable change in metabolism. Radiation of the cervical region produced no change other than an immediate fall in the urinary creatinin, attributed by the authors to temporary paralysis of the parathyroids. On the other hand, radiation of the abdomen and spleen produced definite urinary and blood changes which are set out in tabular form in the authors' article. The metabolic changes can be best explained by a temporary inhibition of the functions of the three principal abdominal glands—namely, the liver, pancreas, and kidneys—the fall in urea content of the blood being outside the picture. The figures give no support to the theory of acute uræmia recently enunciated by ANDERSEN and KOHLMANN, which was the starting-point of the authors' investigation; but they do give some support to LANGE'S theory of acidosis, in view of the fact that the ammonia coefficient definitely rises as a result of radiation.

In the light of the metabolic changes which they observed, Dr. DODDS and Dr. WEBSTER suggest the possibility of prophylactic measures, which are to form the basis of a further investigation. Administration of calcium chloride or sodium bicarbonate before radiation has already in some cases resulted in a diminution of the ensuing reaction. The whole plan of work should be studied very carefully by all who are occupied with the application of X rays or radium to any part of the body, for the authors discuss in an objective and dispassionate manner all the theories hitherto advanced to explain the incidence of radiation toxæmia, and their scholarly contribution should materially clear the way for later workers. The discussion on the clinical results of deep X ray therapy, announced for March 21st at the Royal Society of Medicine, will benefit by starting from some such sound pathological basis.

[1] THE LANCET, Feb. 16th, p. 344.

PROPOSED ALTERATIONS IN THE LAW OF THE FAMILY.

PARLIAMENT has before it at the present moment an unusual number of measures affecting the law of the family. Of these Lord BUCKMASTER'S Legitimacy Bill has perhaps the most hopeful prospects, for both the Prime Minister and the Lord Chancellor have stated that it has the approval of the Government. If the principle of *legitimatio per subsequens matrimonium* is now adopted in England, it will repeal one of the oldest Acts on our statute-book; but very few other countries have agreed with us on the point, and we ourselves would probably have changed our law last year but for the dissolution of Parliament. Lord BUCKMASTER proposes that "legitimated persons" shall be able to inherit property on intestacies, and that in future wills the words "child" or "issue" shall include legitimated children unless the contrary intention is expressed. Lord PHILLIMORE would reject the clause which says that the Bill shall not affect the succession to dignities or titles. It certainly seems odd that one person should inherit the ducal estates while another person becomes the duke. In Committee, however, Lord GORELL'S amendment to omit the clause was defeated. The Archbishop of CANTERBURY succeeded in narrowing the Bill to

cases where both parents were unmarried when the child was born. A similar stipulation appears in Mr. WIGNALL'S Illegitimacy Bill, which proposes to consolidate and amend the Bastardy Acts and kindred legislation. This Bill must expect sharp opposition, for in affiliation proceedings it would abolish the need of corroboration of the story of a woman who is the mother of, or believes herself to be pregnant with, an illegitimate child. Some of its provisions might open the door to blackmail.

The Matrimonial Causes Bill is another House of Lords Bill sponsored by Lord BUCKMASTER. It claims to be based on the majority report of the Royal Commission of 1909 presided over by Lord GORELL. In one respect it is not so drastic. The majority report (published in 1912) would have allowed judges to close the court in divorce cases and to order specific parts of the evidence or speeches not to be published; it recommended that no report of a divorce case be published till the case was finished, that all photographing or sketching of parties or witnesses should be forbidden, and that breaches of these provisions be treated as contempt of court. Lord BUCKMASTER merely provides for closing the court at discretion. In more vital matters he accepts the Royal Commission's views completely. The sexes are to be on an equality in divorce proceedings. There are six grounds for divorce: (*a*) adultery; (*b*) desertion for three years; (*c*) cruelty; (*d*) incurable insanity (after five years' confinement); (*e*) habitual drunkenness found incurable after three years from the first separation order; and (*f*) imprisonment under commuted death sentence, to which he adds also confinement in a criminal lunatic asylum. The grounds for pronouncing nullity of marriage are four: (*a*) non-consummation; (*b*) marriage by person of incipient mental unsoundness becoming definite within six months, or by a person who is epileptic or insane; (*c*) venereal disease existing at date of marriage; and (*d*) pregnancy of the wife at date of marriage by some man other than the husband. Under (*b*), (*c*), and (*d*) the applicant must have been ignorant of the facts at the date of marriage, must not have had marital intercourse since discovery of the truth, and must have instituted proceedings within a year of the marriage. Separation orders obtainable from magistrates are limited to two years, after which an extension may be obtained from the High Court; these temporary orders may be granted for cruelty, habitual drunkenness, or venereal disease. Separation and maintenance orders in their summary jurisdiction aspect are also the subject of a Bill brought forward by Sir ROBERT NEWMAN. The latter allows a married woman to apply for an order on the ground of her husband's cruelty and neglect, notwithstanding that such treatment has not caused her to leave him. There is another clause assisting a wife who is driven to prostitution by a husband whose conduct is likely to result and has in fact resulted in her degradation. Adultery by the wife at present discharges an order. Sir ROBERT NEWMAN proposes that this discharge shall not be automatic if the court considers that the husband's failure to make his payments has conduced to the adultery; and, where the magistrates do discharge the order, they may make a fresh order giving the wife the custody of the children and directing the husband to contribute weekly to their maintenance. With Parliamentary time limited by financial debates and by special difficulties of other kinds, it is hard to estimate the chances of changing the law on these points, but it will be recalled that a measure to amend the law of separation and maintenance orders was included in the King's Speech in January.

Mrs. WINTRINGHAM'S Guardianship of Infants Bill is not yet available for perusal. Both Sir M. MACNAGHTEN and Sir THOMAS INSKIP have presented Adoption of Children Bills. The latter's is the shorter and more workmanlike; it provides for the adoption of children under 10 with the approval of the High Court or county court, the court being directed to have regard solely to the interests of the child. The law affecting the family would be strengthened in many respects if the Children Bill were passed which we have previously discussed. In his capacity as private member Mr. AMMON has brought in an Offences against the Person Bill, which goes over again much of the ground covered by the Children Bill, and is perhaps unlikely to make much progress. As both these Bills have important clauses relating to criminal assaults upon young people, it may be hoped that the draftsmanship is satisfactory. The Criminal Law Amendment Act of 1922 had not been many months in force before the Court of Criminal Appeal found that its interpretation involved consequences both favourable and adverse to offenders which Parliament could never have intended. Proposals which are not likely to experience judicial criticism of this kind are contained in the Criminal Justice Bill, which is founded on solid professional and judicial support. The Bill, inter alia, would remove the legal presumption that a wife who commits an offence in the presence of her husband has acted under coercion from him. This presumption is not recognised outside England and is unsuited to an age of sex equality. If it disappears, it will still be possible for the jury to find that in the facts of the particular case the wife was so coerced by her husband. There remains one proposal which will raise less stir than it would have evoked before the passing of the Deceased Wife's Sister Act of 1907 or the Deceased Brother's Widow Act of 1921. Mr. RENDALL'S Marriage (Prohibited Degrees of Relationship) Bill would allow marriage with a deceased wife's brother's or sister's daughter or a father's or mother's deceased brother's widow, or, in plain English, marriage with persons who are nephews or nieces by marriage. Sufficient unto the day when the Bill becomes an Act are the complicated relationships which may ensue from such unions. For some of the prospective measures mentioned above a precedent could be cited from some other part of the Empire. If the Imperial Parliament is beginning to give marked attention to proposals of social reform specially affecting family life, much of the credit must undoubtedly be given to the feminine portion of the electorate, whose numbers it has recently been proposed to enlarge.

THE ACID-BASE BALANCE OF THE BLOOD.

THE automatic adjustments of the human body have often been an object for envy on the part of laboratory workers who find it difficult from a mass of conflicting influences to achieve a constant result. In whatever direction and for whatever length of time the balance is disturbed, there is an invincible tendency to return to the physiologic norm as soon as the disturbing influence is eliminated. This has long been evident with regard to the regulation of the body heat; it is only of recent years that it has been shown to apply to the chemical reaction of the tissues. The exact range of hydrogen-ion concentration of the blood serum which may be considered normal is still in dispute, although it probably lies

between the variations represented by pH 7·3 and pH 7·5. Under exceptional conditions these limits may be exceeded, but a return to normal is rapid and automatic; the extreme variations compatible with life appear to be on the acid side pH 6·9 and on the alkaline side pH 9·0. Beyond these limits presumably life is impossible. The latter figure has only been seen under experimental conditions, and it is probable that a figure of 7·9 is rarely, if ever, exceeded. Wide variations occur in the course of disease and similar variations have been produced experimentally in man. Some remarkable results obtained on himself and colleagues at Oxford and Cambridge were given by Mr. J. B. S. HALDANE at a recent meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine, and are summarised in our present issue. Mr. HALDANE produced acidosis by the ingestion of large doses of ammonium chloride and alkalæmia by similar doses of sodium bicarbonate. After taking 45 g. of $NaHCO_3$ he found that the alkali reserve of the blood might be increased by 20 per cent., the blood becoming more alkaline and ammonia disappearing from the urine. After taking 65 g. of NH_4Cl spread over a period of three days the alkali reserve was reduced to less than half of the normal, the calcium content of the serum rose by 10 per cent., and the excretion of Na, K, Ca, and P was vastly increased. When he took NH_4Cl the body-weight was found to drop sharply and the hæmoglobin in the blood to rise, owing probably to physical change in the body colloids. Dr. ARTHUR ELLIS, who contributed to the same discussion, narrated the case of a patient suffering from alkalæmia as a result of pyloric obstruction who was given three-hourly 10 oz. of 2 per cent. ammonium chloride per rectum for four doses, or about 22·5 g. in all. Before treatment tetany and general convulsions were occurring, the pH of the plasma being 7·6 and the plasma bicarbonate standing at 120. Twelve hours later tetany had disappeared, muscular irritability was greatly diminished, although still present; convulsions had ceased. The plasma pH was then 7·4, the plasma bicarbonate 76. The interesting question remains to decide how long variations in hydrogen-ion concentration artificially produced are maintained. There can be little doubt that by hot baths the alkaline concentration of plasma may be increased to an extent greater than pH 0·1. This was shown by some experiments made by H. C. BAZETT and J. B. S. HALDANE in 1921.[1] Such a change would, however, merely be temporary and the effect would disappear as soon as the individual ceased the over-breathing caused by the temperature of the hot bath. No evidence has been submitted to suggest that the alteration would benefit the patient. The drinking of saline waters in usual quantity and dilution is hardly likely to effect any alteration in the hydrogen-ion concentration of the plasma, inasmuch as the bodily mechanism for dealing with excess acid and alkali is too efficient to be upset by such a relatively insignificant excess in the daily intake of base. Other physical agencies may, however, do so; radiation, for instance, has been shown to produce a temporary disturbance of the acid-base balance in the body.

BY an Order of Privy Council, dated March 3rd, Mr. Edward F. L. Wood, M.P., and Mr. A. G. Church, M.P., have been appointed members of the Medical Research Council. Mr. Wood is appointed to succeed Viscount Goschen, chairman of the Council, who has resigned owing to his appointment as Governor of Madras, while Mr. Church takes the place of Mr. William Graham, M.P., who has resigned his membership of the Council on becoming Financial Secretary to the Treasury.

Annotations.

"Ne quid nimis."

REMINISCENCES OF PAUL EHRLICH.

HAD he lived, Ehrlich would have been 70 on March 14th of this year. This anniversary is celebrated in a book [1] in which his private secretary, Frl. Martha Marquardt, pulls the curtain aside and shows us Ehrlich as he was at home and in his laboratory. We see, not the impersonal giant of science, but a most human person, with the oddities and eccentricities which, when we see them in our fellow beings, make us laugh and love them the more. The picture of Ehrlich, in constant warfare with his cuffs, is obviously drawn by one whose sex usually guarantees immunity from the discomforts of the floating wristband. Ehrlich would stack his cuffs on a hook behind the door, but sometimes, when he had occasion to resume them, they would be left in place while he wrote or worked with test-tubes, and ever with ceaseless patience he would shake his prolapsed cuffs back with unconscious gestures. At other times he would hold both arms aloft and shake them, hoping that force of gravity would succeed where more than a hundred instinctive jerks had failed. His right-hand man, Kadereit, was everywhere and did everything, from opening his letters to attending to the numberless duties of a laboratory assistant. When Kadereit spoke of "our having discovered salvarsan," he gave expression to the sense of coöperation which Ehrlich's fellow workers enjoyed. Ehrlich had a reputation for forgetfulness in some directions, but he had a positively uncanny remembrance of where he had placed or misplaced things; he knew all about the contents of his numberless bottles, where to find a reference in a stack of books, and where to unearth odd sums of money he had tucked away. Sometimes there were no such sums to tuck away, for his cigar and book bills were heavy. His favourite books were detective novels, but even a tale of romantic crime did not fix his attention enough to prevent his making, on their pages, marginal notes of chemical formulæ. His sense of music, judged by the ordinary standards, was elementary; he loved the "music" of a barrel organ, and at home after dinner he would get his wife to play simple airs and light waltzes, and the simpler and lighter the music, the more pleased and cheerful he would become. It was at moments such as these that his best ideas came to him. Serious music depressed him, and he would revive from its effects only after a rollicking refrain from "Carmen" or some other favourite. After walking about under the cheerful influence of this music, he would sit down to a game of patience, puffing at the inevitable cigar. He would then proceed to jot down notes of the ideas that had come to him, filling many writing pads. He looked upon this work as the most productive of the day, and it was not till after midnight that he would leave the smoke-laden atmosphere of his working-room, and in his bedroom he would often continue reading and making notes till far into the night. There was only one evening in the week when he did not beg his wife to play to him. This was Sunday evening, when a 30-pfennig copy of the last number of a detective magazine formed an irresistible counter-attraction. About Christmas, 1914, he had a slight stroke, the immediate effects of which passed off in a few days, but he was left a silent and abstracted man. He was deeply distressed over the war, anticipating many of the troubles it would bring to all, and a break in his scientific coöperation with friends abroad. But to the end of his life he sometimes spoke with enthusiasm about future lines of research, and once remarked that even if he did nothing further himself, there were enough ideas jotted down in his note-books to give employment to a dozen chemists for

[1] Paul Ehrlich als Mensch und Arbeiter. By Martha Marquardt. Berlin and Stuttgart: Deutsche Verlags-Anstalt.

years under his direction. A second stroke on August 20th, 1915, suddenly terminated the career of one of the benefactors of mankind.

VENEREAL DISEASE AMONG MENTAL DEFECTIVES.

THE Mental Hospitals Committee of the London County Council has taken exception to a paragraph in the recently published report of the Government Committee on the Prevention of Venereal Disease which runs as follows :—

"There are found to be a considerable number of persons suffering from venereal disease among mental defectives, and the present arrangements for their control and treatment are inadequate."

The committee recognises that there may be an increased risk of venereal infection among the mentally defective, who lack the power of self-control, which tends in the normal person to sexual continence or at least to the taking of safeguards, and it is the committee's experience that mentally defective girls, if not carefully and wisely controlled, are prone to moral lapses. They, however, point to the reports issued by Sir William Hamer, who has emphasised the fact that there is comparatively little evidence as regards the incidence of primary venereal disease amongst the mentally defective, and that the number of defectives notified under the Mental Deficiency Act—and it is with these alone the L.C.C. is directly concerned—who have been found to have the disease is small and confined to cases notified from refuges, hostels, hospitals, or prisons. The L.C.C. committee is of opinion that the measures contemplated by the Act for dealing with defectives—e.g., supervision or institutional care or guardianship—should give all necessary protection against risk of venereal infection to those who are dealt with. If a defective under supervision or guardianship cannot be kept under such control as will keep him or her free from infection, institutional care ought to render the risk negligible. There may, however, be a difficulty with high-grade cases of mental defect whose social circumstances are such that they cannot be regarded as subjects to be dealt with by the local authority, and who therefore do not come within the purview of the Act. The Mental Hospitals Committee finally state that, as far as their own experience goes, there does not seem to be any special justification for the very wide statements made in the paragraph quoted.

JAUNDICE IN ENTERIC FEVER.

MM. Garnier and Reilly[1] remark that the idea of a typhoid or paratyphoid origin for the majority of cases of acute jaundice was at one time widely accepted in France, so that in any case of acute jaundice examination of the blood and stools for organisms of the typhoid group as well as Widal's test was always carried out. The discovery of *Spirochæta icterohæmorrhagiæ* threw new light on the pathogenesis of infective jaundice, but the origin of the most frequent variety of acute jaundice—viz., the catarrhal or acute apyretic form—remained obscure. In a study of 1300 cases of acute jaundice the writers found only four which could be attributed to typhoid or paratyphoid infection, so that they have come to the conclusion which agrees with the observations of the old clinicians that jaundice is extremely rare in enteric fever. The symptoms were identical in their four cases. The clinical picture was that of typhoid fever complicated by jaundice, which was always of slight degree and accompanied by the ordinary symptoms of typhoid infection. The discrepancy between the writers' observations and those of previous observers is to be explained by the fact that the laboratory tests employed by the latter were unsatisfactory in a large number of cases. As regards the outbreaks of epidemic jaundice which occurred in the war—e.g., in the Anglo-French armies at Gallipoli in 1915 and later in the French army in Macedonia, the Roumanian army in the Balkans, and the Italian army on the Isonzo—Sarrailhé and Clunet, and Cantacuzène and his collaborators attempted to make paratyphoid bacilli responsible owing to the frequency of bacilli of the paratyphoid group in the blood and stools. The writers, however, point out that the organisms were atypical. Thus, in the Roumanian epidemic the organisms isolated belonged to 14 different strains. Moreover, the extreme degree of contagiousness and the short duration of the incubation period completely differentiated the disease from enteric. The frequency of epidemics of jaundice in the Roumanian troops who had been inoculated against enteric fever and their absence in the uninoculated Turkish soldiers cannot be explained, as Sacquépée suggests, by the paratyphoid infection showing a preference for incompletely immunised subjects, as jaundice was rarely observed during the paratyphoid epidemic in the incompletely immunised French army during 1915 or in the cases of typhoid infection among the inoculated observed by Bernard and Paraf, Labbé, Rist, and others. The writers remark that the view of the paratyphoid origin of epidemic jaundice is by no means so popular in other countries as in France; it has been rejected by C. J. Martin and Sir William Willcox in England, Benczur and Beyreis in Germany, and Kampf and Wornoe in Denmark. The writers conclude that jaundice in enteric may be met with under two different conditions—viz.: (1) exceptionally in patients with typhoid or paratyphoid running an ordinary course, (2) more frequently in individuals who have been subjected to a massive infection either accidentally, as in alimentary intoxication, or experimentally, as was carried out by Cantacuzène.

THE SANATORIUM AS A RESEARCH CENTRE.

IT would probably be unwise to accept as more than a caricature the picture of a sanatorium superintendent presiding over a cabbage patch, on which patients practise graduated labour, fulfilling his duties as a sort of house physician to the outside tuberculosis officer with the zeal, or want of zeal, that a subordinate station in life evokes. But the administrative blunder which has robbed the sanatorium superintendent of the last word as to the duration of a patient's residence in a sanatorium has inevitably acted as a brake on therapeutic initiative and independent research requiring continuity of observation in certain individual cases. It is therefore a pleasant surprise to find that, in spite of this obstacle, important research is being carried out here and there by enterprising sanatorium superintendents with a scientific bent. An example of such work is to be found in the fifth annual report of the Glenlomond Sanatorium, Kinross. The medical superintendent, Dr. W. T. Munro, has evidently followed the recent investigations in Berlin by Prof. Uhlenhuth, on whose observations on immune sera in the treatment of tuberculosis we have recently commented.[1] Dr. Munro has attempted to reduce the pulse-rate in very toxic cases by injecting the serum of patients who were doing very well. Naturally due regard was paid to the blood groups, and only Wassermann-negative sera were used. In one case the patient's pulse was reduced from an average of 110 to 80–88 every time serum was given. On the suggestion of Sir Robert Philip inunction with a tuberculin ointment has been given in cases of tuberculosis of the glands, and Dr. Munro writes that "we are more impressed with the treatment of massive tuberculous glands by this means than by any other." At the time this report was written about 30 patients were undergoing treatment with Prof. Dreyer's diaplyte vaccine, but of the value of this remedy Dr. Munro reserves his opinion. Of other

[1] THE LANCET, 1923, ii., 943.

modern remedies, collosol calcium has been given an extended trial and has been given up. Dr. Munro has, indeed, never found any drug of any material value in the treatment of pulmonary tuberculosis, and this is a verdict with which probably most sanatorium physicians would reluctantly agree. Some curious observations were made in six cases of hæmoptysis. In every case a hæmolytic streptococcus was found in the sputum, and after these patients had been treated with autogenous vaccines, all improved, and not one has again had an hæmoptysis. Several cases of asthma were investigated on the lines laid down by Noon and Freeman, and an interesting case is related of an epileptic patient who was found sensitive to a coliform bacillus passed in the urine, and who was given an autogenous vaccine. Under this treatment the fits, which had occurred on an average twice a day, were reduced to one per week, tubercle bacilli disappearing from the sputum and the weight increasing by a stone. The serological characteristics of 100 specimens of tubercle bacilli, obtained from the patients' sputum, have been investigated and found to belong to one and the same group. The Fife and Kinross Joint Sanatorium Board is associated in its scheme of research with Prof. W. J. Tulloch, of Dundee, and this association is doubtless of reciprocal value. There are few sights more pathetic than that of a research worker ploughing a lonely furrow without the benefit of that stimulus which rubbing shoulders with other workers provides. And the value of the sanatorium as a research centre is doubtless greatly enhanced by its being linked up with some other centre at which observations can be checked and verified.

EYELESS SIGHT.[1]

Jules Romains, less known as a physiologist than as a dramatist and literary artist who is not altogether enthusiastic about the medical profession, believes that the general skin surface of the body and some of the adjacent mucous membranes are capable of vision in the sense that completely blind or blindfolded people may recognise colours, persons, geometrical forms, and even read the newspaper by means of their skin. He identifies as accessory eyes some of the many varieties of end-organs in the skin whose precise function has never been determined. The phenomena which he describes are certainly striking. There is no inherent impossibility in the idea that the skin is responsive to the wave-lengths in the ether which we recognise as light, and if there are receptors scattered over the surface it is conceivable that these impressions might be translated into conceptions of external appearances. But a world steeped in the dogmas of physiological optics will require more rigorous proof than the author advances. One pitfall at any rate is quite insufficiently fenced-off. With one exception, the experiments which he cites take no account of telepathy, the object or word or numbers presented to and recognised by, e.g., the chest of the subject being known to someone else who was actually present. If he would take Prof. Richet into collaboration, we could be sure this source of error would be adequately excluded. That telepathy is the explanation of his results is certainly supported by his observation that some degree of attention and the correct frame of mind are necessary for success. The same is, of course, true of common ocular vision, and Mr. Romains makes several points which are frankly against a telepathic interpretation. Success varies roughly with the area of skin exposed, and the skin cannot see in the dark (though the experiments on this point seem a little vague), nor if anything opaque to ordinary light is interposed between it and the object. There is nothing remarkable in his observation that paroptic sight is possible only in the complete absence of ordinary visual sensations. On his thesis in general the only possible comment seems to be, "It may be so." People talk easily of the blind men who find their way so quickly and surely about the streets having developed another sense. Perhaps Mr. Romains has identified it.

GANGRENE OF EXTREMITIES IN PUERPERAL FEVER.

Dr. Victor E. Chesky,[1] of Halstead, Kansas, who records an illustrative case, remarks that puerperal peripheral gangrene, while not common, is liable to occur in any case of puerperal sepsis or septic abortion. Stein in 1916 collected 76 cases, including two of his own, in 63 of which gangrene followed labour, and in four septic abortion, while four occurred during pregnancy, and five followed gynæcological operations. Knipe in 1917 recorded another case following septic abortion, so that with Dr. Chesky's case there are now 78 examples of obstetrical or gynæcological interest on record of gangrene of the extremities. In most cases one or both of the lower extremities was involved. Much less frequently the upper extremities were affected. In only one instance was there symmetrical gangrene of the fingers, toes, and ears. The causative factor in puerperal peripheral gangrene is always infection, which may vary from a very mild form with a low temperature lasting only a few days to the most severe type of puerperal sepsis. Either a streptococcic or a mixed infection is present. The circulatory block is usually situated in the arteries. Puerperal gangrene of venous origin is relatively rare. Contributory causes of thrombosis are low blood pressure and sluggish blood-stream, caused by severe hæmorrhage or weakened heart action, recumbent position and relative immobility of the body, lowered resistance against infection, and abnormal constitution of the blood. The prognosis is bad, the mortality being about 50 per cent. Early amputation of the gangrenous part is the most important step in treatment. Dr. Chesky's case occurred in a vigorous primipara, aged 19, in whom puerperal sepsis developed on the day after delivery. Five days later she complained of numbness in both feet, which became swollen. Dry gangrene of the toes developed and complete recovery followed their removal. Dr. Chesky attributes the gangrene in his case to arterial occlusion, the thrombus being localised in the pelvic vessels.

PURE ETHER.

Prof. Storm van Leeuwen, of Leiden University, in his paper to the Section of Anæsthetics of the Royal Society of Medicine on Friday of last week gave some conclusive evidence as to the narcotic effect of pure ether. The opening of his address showed how the inability to procure ether from Germany, from which country Holland had been accustomed to draw its supplies, gave Dutch manufacturers a new keenness in the production of the drug. Consequently, when there came from England the expressions of doubt as to the efficacy of pure ether, research workers in Holland were besought by the manufacturers for guidance. Thus it was that Prof. van Leeuwen started his admirable, and, as it appears to us, well-nigh unanswerable investigation. Having first of all procured from pure ethyl alcohol the purest ether he could, which boiled at 34·6° C., and having found that this had true narcotic effect, the Professor decided that even with this specimen the narcotic qualities might be attributed to minute impurities present. He prepared, therefore, by the use of benzidene, which crystallises with ether when they are heated together and then cooled, crystals which, when heated, gave an ether of absolute purity. This drug, which had the same boiling point as his former product, proved to be a good narcotic. It was carefully tested both quantitatively and qualitatively on both animals and on man. A series of animals were rendered narcotic with it, observations

on the blood content of ether being made at various points of the narcosis up to that at which the respiratory centre failed. With regard to the effect of impurities in ether, it appeared that, in the small amounts present in ordinary good brands, these play no part in the anæsthetic action of the drug. The only reason for adding any other drug to ether is to render it stable, for pure ether, if kept exposed to light and air, becomes contaminated with peroxides. This happens with ordinary good ethers, but not with the ether of crystallisation, or with ethanesal or Cotton's ether. In the discussion which followed Prof. van Leeuwen's paper Dr. H. H. Dale expressed his concurrence with all the findings described in it, and declared that the apparently opposite conclusions arrived at by Dr. Mackenzie Wallis and Dr. Langton Hewer could only be explained by the assumption that the drug they tested was not the same drug as that tested by himself and by van Leeuwen. Consequently he invited Dr. Wallis when next he had prepared a pure ether which he found to be non-anæsthetic to allow Dr. Dale and his co-workers to have samples of it and test it in conjunction with Dr. Wallis.

MALARIA THERAPY IN GENERAL PARALYSIS OF THE INSANE.

A WARNING as to the need of caution in the experimental treatment of general paralysis by the inoculation of malaria was the subject of a considered article by Prof. P. Mühlens, of Hamburg, in the *Klinische Wochenschrift* of Dec. 24th, 1923. Indiscriminate use of this method in private practice is strongly condemned, and even in hospitals the new treatment should not be entrusted to any neurologist who has not made himself thoroughly familiar with the clinical symptoms and signs and the parasitology of malaria. Prof. Mühlens points out that the inoculations should only be carried out on individuals whose resisting powers are good and whose paralysis is not of too long duration. The earlier the treatment is started the better are the prospects of success. Before inoculation of a patient it should be ascertained that he can easily take quinine. For malaria inoculation only a pure benign tertian strain should be used, and the progress of the blood infection should be controlled by daily blood tests, in order that when necessary the infection may be checked in time. When it appears from these examinations or from the condition of the patient that the blood infection has suddenly become very severe, quinine should immediately be given. Those treated with malaria should not be allowed to leave an institution before they have been definitely free from parasites for at least three or four weeks. Most of the malaria inoculation deaths which have come to the author's knowledge concerned ill-nourished elderly paralytics, or those whose infection was not continuously and expertly controlled, or who were not early enough treated with quinine. Prof. Mühlens's warnings are based on his desire to avoid bringing into discredit a therapeutic measure which he considers the best method of treatment for general paralysis. He claims that a very high percentage of paralytics treated with malaria and relapsing fever infection have remained for years capable of work and free from relapse.

A memorandum recently issued by the Board of Control draws attention to the differences, some of them important, between the procedure adopted for carrying out the treatment in England and Wales and the procedure which has been usually recommended by the initiators of this therapeutic measure in Austria, and a plea is entered for uniformity of procedure and practice at least in all the British hospitals where trials are being arranged, in order that the merits of the treatment may receive fair consideration. It is recorded that in some instances the induced malaria in the inoculated cases in England has been of an unusually severe type accompanied by pronounced complications and with a tendency to fatality. It is hoped that a strain of parasites which is free from objection on grounds of severity will be available shortly, but in any case if the blood of all inoculated patients is examined daily the occurrence of untoward symptoms and complications may be avoided. This procedure is also required in connexion with the risk, to which Prof. Mühlens draws attention, of unwittingly conveying a mixed infection of benign and malignant parasites from donors of blood who contract their malaria in the tropics. Since it has been shown that the common malaria-carrying mosquito of England (*Anopheles maculipennis*), after sucking blood from inoculated patients, readily becomes infected and capable of spreading malaria to other patients and to the general public, it is essential to take adequate measures to avoid this risk. During the summer months (April to October inclusive) inoculated patients should be kept in a mosquito-proof ward, or under satisfactory mosquito curtains, from the onset of the malarial attacks until careful microscopical blood examination shall have proved that the blood is free from the sexual forms of the parasite. This will usually be the case about three days after commencing a proper course of quinine treatment. As to the danger of relapse it has been contended that an entire absence of relapses is a particular feature of inoculated malaria. In this country, however, what are technically known as "parasitic relapses" have been detected by examination of the blood of patients some weeks after apparent clinical recovery, and in order that these patients should not provide a potential source of spread of malaria it is recommended that blood examinations should continue until freedom from parasites has lasted at least three weeks. It is also considered necessary that, when a patient who has undergone a course of malarial attacks is discharged from the hospital, his name and home address should be notified to the medical officer of health of the district to which he is discharged. The importance of effective quinine treatment and "after-treatment" in the interests equally of the patients and of the public is emphasised.

Details of observations on the blood and cerebro-spinal fluid of 40 patients with G.P.I. treated by inoculation with malaria are recorded in our present issue by Dr. A. R. Grant and Dr. J. D. Silverston. Sixteen of the patients received in addition a course of salvarsan, after the malaria had been arrested by quinine. A decrease of the lymphocytosis and in the globulin content of the C.-S.F., and a diminution in the intensity of the W.R. occurred in nearly half the cases. The W.R. of the C.-S.F., the colloidal gamboge reaction, and the colloidal gold test were favourably influenced at a somewhat later period in a smaller number of cases. The observers are content to record their findings at this stage without comment.

A NEW SERIES OF MEDICAL FACSIMILES.

AN interesting experiment has been made in medical publication by the Oxford University Press acting in conjunction with Messrs. Lier and Co., of Milan. They have produced[1] in photographic facsimile the excessively rare and finely illustrated folio first edition of the "Fasciculus Medicinæ" of Johannes de Ketham, printed at Venice in 1491. This edition, which had a larger page than any of the subsequent issues, is historically important as representing the turning-point for medicine from the Middle Ages to modern times. Beside the facsimile of a remarkable work the volume before us contains also an elaborate account of its sources and affinities, written by Prof. Karl Sudhoff, of Leipzig, and adapted for English readers by Dr. Charles Singer. Of the series of 14

[1] Edition de Luxe, bound in half leather with eight plates coloured by hand, £3 10s. A cheaper edition at £2 6s. identical with the first save that only one plate is coloured and the binding is half linen. The actual printing and publication is the work of Messrs. Lier, of Milan, for whom the Oxford University Press are acting in this country.

plates drawn from manuscript material, eight have been coloured by hand. Should this beautiful issue of a remarkable work prove successful, the proposal is to produce a whole series of facsimiles of early medical works. The second edition of the "Fasciculus," printed in Venice in 1493, with its woodcuts by the artist of the famous "Hypnerotomachia Poliphili," has been for some time in the press under the editorship of Dr. Singer. The ten earliest fifteenth century tractates on syphilis are almost ready and other volumes have been planned. The series, which is entitled "Monumenta Medica," is under the general editorship of Dr. Henry Sigerist, of Zurich.

HOLES IN A DETACHED RETINA.

THIS is a condition more often talked about than seen ophthalmoscopically, and when seen has generally been regarded as merely an interesting phenomenon without special clinical significance. A paper in the January number of the *British Journal of Ophthalmology*, by Sir William Lister, contains generalisations which will clear up a number of perplexities in connexion with this condition. The first is that sudden detachment of the retina cannot occur without a hole, a fact first mentioned by Leber in his lectures at Heidelberg in 1882, of which, according to Lister, too little notice has been taken. If we come to think of it, however, the onset of any detachment of the retina without a hole must necessarily be gradual. Transfer of fluid from the vitreous chamber into the inter-retinal space cannot be sudden unless there is a hole. Should there be a hole transfer must be rapid and loss of vision correspondingly sudden. If, therefore, it can be substantiated that the loss of sight from a detachment was not merely suddenly detected, but actually occurred suddenly, we can definitely predict the presence of a hole, whether or not it can be seen by the ophthalmoscope. A second important generalisation is that no cases of detachment of the retina due to neoplasm, when examined pathologically, have been found associated with a hole in the retina. In these cases the detachment is secondary, and due to the exudation of an albuminous fluid quite different from the vitreous, which in cases where a hole is present naturally finds its way through it to the inter-retinal space. We may therefore safely assume that in any case of detachment where a hole is seen by the ophthalmoscope, the presence of an intra-ocular tumour can be excluded. A third point of clinical importance discussed by Sir William Lister is the value of treatment of detachment of a retina in which there is a hole. In any case of detachment treatment is most uncertain in its results. There are few ophthalmic surgeons who could not count all the cases of undoubted cure coming within their experience on the fingers of one hand. Yet, when treatment is successful, the boon to the patient is inestimable. On the other hand, if treatment is attempted at all it is of necessity very irksome to the patient and may involve a waste of valuable time for no good purpose. Therefore the value of Sir William Lister's experience on this subject is considerable. Where the retina is being dragged in by vitreous bands, treatment, or at any rate, any ordinary treatment, is valueless, for even if apparently successful for a time, the condition is certain to recur. When, however, the retina is being pushed in by fluid poured out from the choroid into the inter-retinal space, owing to some low form of inflammation, treatment may be legitimately tried and in rare cases may be successful. Operative treatment in the presence of a hole must necessarily be unavailing, except in the rare cases of peripheral and strictly localised detachment where the affected portion of retina is completely cut off from the rest by adhesions. It is true that some years ago a committee of the Ophthalmological Society [1] reported that among cases of cure investigated there were three (apparently not as the result of operation) in which tears of the retina had been present, and it is difficult to reconcile this with Sir William Lister's generalisation. This aspect of the subject might claim attention from those who have studied detached retina in the past.

[1] Trans. Ophth. Soc., 1916, xxxvi., 354.

XANTHOMA DIABETICORUM.

ACCORDING to Dr. Ralph H. Major,[1] of the Department of Internal Medicine, University of Kansas School of Medicine, who has collected 74 cases from the literature, as well as three under his own observation, xanthoma diabeticorum was first described by Addison and Gull in the Guy's Hospital Reports in 1850. The condition is most frequent in the male sex, and comparatively uncommon in women, among whom only about ten cases have been recorded. As a rule, it disappears with improvement in the diabetes, although some exceptions have been noted, in which the skin lesions remained stationary or actually increased, in spite of the urine being free from sugar. Bristowe, who reported the second case on record in 1866, described the lesions as showing microscopically a dense fibrillated texture, studded more or less with oil globules of different sizes. Comparatively few observations have been published upon the appearance of the blood or upon the blood chemistry of these cases. Dr. Major's cases, therefore, are of special interest, in that studies were made of the blood-sugar and cholesterol, particularly in relation to treatment by insulin. The first patient was a Jew, aged 43, with a very profuse eruption of xanthoma, who was admitted to hospital with diabetic coma and died a few hours after admission. The blood serum was milky-white and presented a gross lipæmia, and the cholesterol in the blood-plasma was 432 mg. per 100 c.cm. In the other two cases the xanthoma cleared up under the influence of two factors—viz., (1) the disappearance of lipæmia and hypercholesterinæmia as the result of insulin treatment, and (2) the presence of a food supply to the lesions afforded by local injection of a small quantity of ether. Histological examination of excised nodules in the two cases showed a marked fibrosis with infiltration of small mononuclear leucocytes, the xanthoma cells being inconspicuous. A study of sections of the tissue indicated that the xanthomatous nodules were composed of neutral fat, fatty acids, and lipoid bodies, and contained cholesterol.

[1] Johns Hopkins Hospital Bulletin, January, 1924.

AT a meeting of the governors of St. George's Hospital on Monday last H.R.H. Prince George was elected President of the hospital, a post which has been vacant for nine or ten years, having been last held by Princess Christian.

WE regret to announce the sudden death on March 9th of Mr. George Palmerston Newbolt, senior surgeon, Royal Southern Hospital, Liverpool, and newly appointed President of the Liverpool Medical Institution.

MANY of our readers will have seen with lively concern the news that Sir StClair Thomson was among those injured in the accident to the Ventimiglia express near Lyons on March 10th. We are happy to be able to reassure them that his injuries were slight and that he hopes shortly to resume his journey to the Riviera.

UNDER a scheme arranged by the University of London for the exchange of lecturers between England and Holland, Dr. E. Gorter, professor of pædiatry in the University of Leiden, will deliver a lecture to advanced students of pædiatry at the Hospital for Sick Children, Great Ormond-street, W.C. 1, on March 19th at 5 P.M. The subject is the Pathogenesis of Certain Nutritional Disorders, and the lecture will be given in English, illustrated by lantern slides.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXII.

MASTURBATION IN YOUNG CHILDREN.

MASTURBATION in infants and young children is probably more common than is generally supposed. It begins sometimes as early as the sixth month, more often during the second year. Thereafter we may meet with it at any time up to or beyond puberty. Treatment will here be considered only of cases in children under 7 years.

The act is performed in various ways—by friction between the adducted thighs, by direct manipulation, or by pressing against the projecting edge of some object such as a chair or table. If thwarted in the attempt, the child may show great restlessness and irritability. If the act is completed, excitement and flushing of the face give way to a strange, drowsy state, with an expression on the child's face which shocks and alarms the mother. It is not easy in such a case to give effective treatment, and yet we may be certain that here, as in enuresis and many other functional nervous disturbances in children, treatment lightly embarked upon which fails of its effect, does more than fail. For failure of treatment which concentrates the child's attention upon the objectionable habit, thereby greatly increases the difficulty of securing ultimate success.

I think it may be best to discuss the subject of treatment under the following heads: (1) The explanation to be given to the mother; (2) the attitude to be adopted to the child; (3) apparatus for restraint; (4) the control of local irritation; (5) the prescription of sedatives.

1. *The Explanation to be Given to the Mother.*

Generally we find that the mother is in a state of extreme distress. The action of the child appears to her sinful, alarming, or altogether horrible. She is conscious of her powerlessness to forbid or to control. In all other matters the child may be docile, affectionate, and responsive to the mother's influence. But on this point the mother has, as it were, lost her nerve, and the child feels the sense of unrest. I have known a little girl compelled to give way to the impulse turn to her mother, and then, conscious of the look of unhappiness, wail out, "Smile, Mummy." The mother's power to control is inhibited because she regards the habit as showing a precocious and unnatural sexuality. It is well to begin by explaining the extreme frequency of masturbation and its comparative harmlessness. Symptoms of exhaustion occur only when the act is performed almost incessantly during day and night. Children have no knowledge of all that sex implies to the mother's mind. They will admit to the practice openly and without shame or embarrassment. They will say that it gives them a comfortable feeling. The infant before the intellectual life awakens, before recollection of yesterday's happenings and anticipation of to-morrow's is possible, is prone to solace its moments of vacancy by stimulating certain sensory nerve-endings. One baby will suck its thumbs, another will bang the occiput from side to side on the pillow, another will practise air-swallowing, or the still more difficult art of rumination. As the level of the intellectual pleasures rises these lower physical stimuli tend to lose their appeal. In general, they are kept in being only when persistent efforts are made to forbid and to thwart. Reiterated appeals and apparatus of restraint have the disadvantage that they keep the desire in the forefront of consciousness. Relief from the impulse only comes when the mind is otherwise occupied. Masturbation, the mother should realise, is comparable to head-banging or thumb-sucking. The child has lit upon this particular form of sensory stimulation, and until made aware of the curious stir among grown-up people to which this particular act gives rise, it is practised openly and without shame. The first essential for cure is to banish from the mother's mind the conviction that the child is displaying vicious and criminal propensities which foreshadow a life of sexual excesses and sexual perversions. If she can take a reasonable view of the trouble, we have then made an ally of the strongest force in the child's life.

2. *The Attitude to be Adopted to the Child.*

I believe that, in general, the best attitude to adopt to the practice is that it is a deplorable breach of manners, a disgusting habit like spitting or picking the nose. It is right that we should endeavour to provoke in the child a sensitive æsthetic sense which is altogether offended by the act. The faces around the child may show a proper proportion of disgust. But we must be careful to hide that we are alarmed or disquieted by the act or utterly cast down by it. Reiterated appeals to a child to desist from a practice which is causing grief to everyone, nightly repeated urgings to show strength and self-control, are useless. I think we can take it for granted that a little child is not likely to show sufficient self-control to resist successfully once the mind is directed towards the thought. Punishment with little children has no part to play in the treatment. It is ineffective as a deterrent, and carries with it the drawback that the children will be tempted to lie to avoid it. If the child is frank and open about the failing, treatment is rendered easier and much is gained. If the act is practised furtively and in fear, it is more difficult to eradicate because, however hard the parents may play the detective, they can never be sure of their ground and must always be in doubt as to the measure of their success. It is as unwise to show anger as it is to show alarm. As with their elders in similar predicament, the best means of defence is flight to other thoughts and occupations. Change of scene and new and suitable companionship are often at once successful in diverting the child from exclusive concentration upon the ever-present temptation. Separation from a mother whose influence cannot be utilised for good may be necessary. Someone who can make the child's life full, busy, and absorbingly interesting, is sure to succeed.

3. *Apparatus for Restraint.*

It is not often, if we have to deal with parents who can carry out a plan such as is suggested above, that we shall fail to get the child's mind diverted from the obsession. The cure of masturbation in the child is to a great extent dependent upon our power to control the atmosphere in the home. Apparatus for restraint need, and I think should, only be used when that control is clearly impossible of achievement. The particular form of restraint, of course, must depend upon the method by which the act is carried out. If the thighs are rubbed together at night or when lying down, it will be enough to adopt any apparatus which prevents the movement—for example, bracelets of webbing, worn above the knees and carrying between them a bar of light metal or wood. If it is practised by manipulation, the hands must be restrained. At the worst, confinement in poroplastic or plaster, such as is worn for spinal caries or poliomyelitis, may be necessary. But whatever device is adopted which mechanically prevents the act, I believe it is of the first importance for success that the child should in no way connect the apparatus with its real object. I believe it is worth while taking endless trouble to convince a little child that his legs are so crooked or his back so one-sided that the apparatus has to be worn to correct the deformity. The desire only passes when the child has forgotten all about it. If the apparatus serves only as a reminder of past excesses, and a prison from which he is powerless to escape in order to indulge once more, then the final removal of the restraint is quite likely to be followed by a giving way all the greater because of the long repression. All the interest and attention

may be concentrated upon the imaginary weakness, while the real enemy sinks out of sight. In young children, with the cessation of the act for some months, the likelihood of relapse is small unless the memory of it has been kept alive by the consciousness of restraint and the daily repeated efforts to prevent. In this connexion I have had one interesting and instructive experience. Almost the worse case I have encountered completely ceased during and after operation for a severe attack of appendicitis. The interest was focused elsewhere. On the other hand, the operation for circumcision, often recommended, has the disadvantage that it directs attention to the sex organs. The operation is not of itself in any way preventive or curative, and should, I think, be avoided when possible. It should be performed only if there is much local irritation under the prepuce, and other means to allay it are unsuccessful.

4. The Control of Local Irritation.

I think that the part played by local irritation in keeping up masturbation is slight. It is true that in the past the original act may have been determined by some irritation of prepuce or vulva, but when our advice is sought that is probably ancient history. Any redness or swelling locally is usually the result and not the cause of the masturbation. With little girls especially, the mucous membrane of the vulva may be red and sore. Painting freely with a weak silver nitrate solution, 1·5 per cent., may harden and desensitise, but if this is done with a little child, it is well to make pretence of similarly painting (this time with water) of nose, mouth, ears, &c., as well if by such a plan the attention of the child can be diverted from the sexual organs exclusively. If the urine is too acid, it can be neutralised with potassium citrate 20 or 30 gr. per diem. Thread-worms should be eradicated, but I have not found them often present.

5. The Prescription of Sedatives.

Children who masturbate early are more often than not unusually quick, vital, and far advanced for their age. Often there is evidence of exhaustion and overstrain, which renders them irritable, and for the time being prone to masturbate. The nervous exhaustion is clearly as much the cause as the result of the masturbation. It is well that sleep should be deep and long. Chloral hydrate has the great advantage over potassium bromide that it acts almost at once. Five grains of chloral will generally produce sleep immediately in a child of 2 years of age, while small doses of bromide may be combined with it, in the hope that thereby a gradual quieting of the child may be produced.

THE DIFFERENTIAL DIAGNOSIS AND THE PREVENTION OF SMALL-POX.*

BY A. F. CAMERON, M.D. EDIN., D.P.H. CAMB.,
MEDICAL SUPERINTENDENT OF RIVER HOSPITALS AND AMBULANCE SERVICE, METROPOLITAN ASYLUMS BOARD.

THE DIFFERENTIAL DIAGNOSIS OF SMALL-POX.

WITH few exceptions, in cases in which small-pox is in question, we have to rely mainly on our personal observation of a rash which in type more or less closely resembles the rash of small-pox. In the great majority of such cases there is at the time of examination no other evidence available which is of any real value, and in making our diagnosis we are compelled to depend on our estimate of the differential value of the cutaneous signs of small-pox and on that alone.

I do not mean to suggest that no value attaches to the symptoms and signs of the onset of the disease or to the character of the pre-eruptive stage. A history of the occurrence of the classical features of the small-pox invasion may be obtained from the patient; previous cases of the disease may have occurred or one may obtain a definite history of contact with the infection. But there is no symptom or combination of symptoms in the onset of small-pox which has intrinsic value in differentiation. Their evidence is of corroborative value only in the presence of a rash which is suggestive of small-pox, and care is necessary to avoid an over-estimate of this value. The signs of previous vaccination have a very limited value as negative evidence when small-pox is in question. The tendency is to over-estimate this value. Old scars, scars which have lost all pigmentation, have no value. If recent and still active lesions of vaccinia are present, one must remember that small-pox and vaccinia may run their course together. Successful vaccination is possible as late as the last days of the period of incubation. On the other hand, there is not, I believe, any reason to doubt that a successful inoculation of vaccinia made in the presence of a doubtful rash is a sure sign that one is not dealing with small-pox.

* Read at a joint meeting of the Home Counties Branch and the Fever Hospitals Medical Service Group of the Society of Medical Officers of Health, Jan. 25th, 1924.

Types of Eruption of Small-pox.

In rare cases the lesion or lesions of inoculated small-pox may be observed at the onset of the disease, and when associated with a definite history of contact with the infection, they are naturally of the greatest assistance in diagnosis.

Small-pox is capable of producing three distinct types of eruption, erythema, purpura, and a focal lesion which is really a vesicle. The erythematous and purpuric eruptions are associated with the primary fever, the erythema more closely with the early period and the purpura with the later period of this stage of the disease, while the focal rash begins to appear towards its end. The coexistence of erythema and a purpuric rash or the imposition of purpuric lesions on an erythema during a short period of observation will suggest the possibility of the presence of small-pox. The association of an erythema in a similar way with an eruption of the focal type will very strongly suggest small-pox, and if the combination of a focal eruption with a purpuric rash occurs, then the diagnosis of small-pox is very frequently correct and the gravest suspicion is always justifiable. It is to be noted that in cases of small-pox which show the last combination particularly, the lesions of the focal rash may be very few and widely scattered and may present few or none of the classical features of the small-pox lesion. They may be flat, dull-white vesicles, oval or perhaps irregular in contour, and apparently of shallow position in the skin. The commonest form of the erythema of small-pox is associated with the mild and modified attack. It is a patchy condition, of indefinite features, varying in the size of its patches, which are irregularly distributed, tending to be evanescent and migratory and not appreciably raised above the surface. This form of the erythema appears on the face only in rare cases, and still more rarely passes further over the face than the surface of the lower jaw and the adjacent parts of the cheeks. It is usually considered that measles is the disease for which this form of the erythema is most apt to be mistaken. But mistakes in this direction do not seem to be frequent and much greater confusion occurs between measles and the early stages of severe confluent small-pox, particularly in the child. A "measles" rash which is distinctly papular may be very difficult to differentiate from small-pox, and isolation of cases of this type for observation is always justifiable.

Erythema Distinctive of Small-pox.

The negative and indefinite characters of this common form of the erythema of small-pox have

obviously little differential value in themselves. They acquire value when associated with a rash of the focal type present at the time of first observation or imposed on the erythema during an observation period of a few hours. In rare cases the erythema assumes more positive features in the disposition of the rash to the surface, in the colour and size and contour of its patches. These cases are toxic in significance and may occur in the course of outbreaks of small-pox of severe type. Large areas of a brilliant colour, almost vermilion at times, may be seen on the extensor surfaces of the larger joints, or extending along the radial surface of the lower part of the forearm and of the hand or along the corresponding surfaces of the leg and foot. These patches are usually symmetrical and may be associated with plaques of a similar character on the trunk. A well-defined margin is a frequent feature of these patches, and sometimes one may find somewhere within an erythematous area on the trunk a papular lesion with hæmorrhage within and around it. This form of the erythema is apparently distinctive of small-pox. Other rare cases occur in which with the onset of the disease the whole surface, trunk, extremities, and face, is covered by a continuous sheet of erythema. In its beginning this rash is very similar in appearance to the flush which may follow a hot bath. It is usually associated with an onset of extreme violence. It is evenly distributed and universal, and in these respects, as well as in the lack of a punctate character, it is unlike the rash of scarlet fever. The beginning of the purpuric rash of the flexures may be a simple erythema from which the colour is easily expressed.

The Purpuric Sign.

These examples of the erythema are toxic in character, and the advent of the purpuric sign is not usually long delayed. The subsequent course of such cases may be dominated by the purpuric lesions which rapidly increase in number and size while the erythema fades, leaving staining. The patient may die without any development of the focal rash. The purpuric lesions by their number and severity appear to usurp the position of the focal lesions. Or the focal rash may appear as a very discrete eruption of hæmorrhagic papules which go on to form vesicles of the type already described, having hæmorrhage within and around them. More frequently the confluence of the focal eruption causes an appearance of swelling of the skin of the face and perhaps also of the hands. The individual lesions cannot be distinguished by touch on the face and only with difficulty on the hands. The skin of the forehead is thickened and immobile and the cause of the condition may not be apparent. But the more discrete foci on the trunk and other parts in such cases are easy to recognise. In very rare cases of this type life is prolonged sufficiently to allow of confluent vesiculation to take place. Extensive tearing of the pellicle may be caused by the restless delirium of the patient, and the case may terminate with the appearance of a severe exfoliative dermatitis.

Mistakes in cases of the most severe toxic type of small-pox may arise on account of the almost complete suppression of the focal rash, or rather the replacement of that rash by purpuric lesions. But in the majority of the cases the extreme severity of the purpura, the association of erythema with purpura, or the imposition of a focal eruption, however discrete, on a severe purpuric rash should be sufficient for diagnosis. The most frequent cause of error is the concentration of the attention on the most prominent feature of the illness, the toxæmia, which is assumed to be sufficient as a diagnosis, and the disease as well as the cause of death is labelled "blood poisoning."

Not much more need be said of the purpuric sign in small-pox. The use of this term is convenient because it includes all the purpuric conditions which may occur, the hæmorrhages from mucous surfaces as well as the hæmorrhages in mucous membranes and skin. It is the sign of toxæmia and it may be found at times in cases of almost every infection. Its manifestation in the skin varies in severity from the slight staining which may be left by the fading erythema or the small bright red petechial lesions which have their site of election in the flexures of the surface to the deep-seated, massive, bruise-like hæmorrhages, and the purple, almost black blotch of a large area of more superficial extravasation. Neither in form nor in position is the sign peculiar to small-pox. The differential value in small-pox depends mainly on a greater average severity in this disease and possibly on a greater average frequency than in other infections. Of the severity of the sign in small-pox, the petechial rash of the flexures is an illustration. Similar rashes may be seen in scarlet fever and in cases of food poisoning. But in small-pox the condition is remarkable for the density of the setting of the petechiæ and also for the extent of the area involved.

A general estimate of the differential value of the sign in small-pox may be expressed in this way: Given the onset of a feverish illness which points to the presence of an acute infection and is accompanied by the purpuric sign, small-pox should be considered to occupy the first position as a possible cause of the condition, and the probability that small-pox is the cause increases with the severity of the purpuric eruption, having regard to the number of the lesions, to their type, and also to the amount of general involvement of the skin.

The Focal Rash.

Ricketts's term for the characteristic rash distinguishes it from the other types of eruption which may occur in the disease. It is a rash made up of a varying number of units or foci pathologically identical. The greater differential value may be ascribed to the features of the unit or to the features of the rash. By his investigations Ricketts showed that the features of the rash, and particularly the position of the lesion on the skin—that is, the relation of the rash to the surface of the body or the distribution of the rash—have a much greater differential value than the features of the unit.

Features of the Unit.

The life-history of the lesion is essentially the life-history of a vesicle which has its origin in a small sharply-defined inflammatory focus in the deeper layers of the epidermis. It is a process of deep-seated vesicle formation. In the typical lesion clinical evidence of the nature of this process begins to appear as soon as the papular element is recognisable. It attains its greatest prominence when vesicle formation becomes apparent. It gradually recedes from view as pustulation advances until at the end of the process, when only the crust remains, the evidence has almost completely disappeared, and the identification of the lesion depends almost entirely on its situation on the surface of the body. Appreciation of the true nature of the process, that it is a deep-seated vesicle formation, will assist in the differentiation of several conditions which are at times mistaken for small-pox, such as most cases of acne and of measles, many cases of urticaria, of secondary syphilitic eruptions, and the lesions caused by insect bites.

Value of Anatomical Evidence.

It is unnecessary for our purpose to consider in detail the clinical evidence by which the nature of the pathological process may be recognised—namely, the evidence of the depth of the focus in the papular and vesicular stages, the observation and meaning of loculation and umbilication of the vesicle, the evidence of the onset of pustulation, the features of the crust, and how they depend on the anatomical character of the skin of the part on which it is situated. The differential value of this anatomical evidence is limited. It is transient. It is based on the anatomical features of the typical lesion which are in continuous change throughout the evolution. It is also dependent on a comparison between these features and those of other focal lesions, and is therefore very subject to the influence of the personal factor of the observer. In

the abnormal lesion, produced by conditions which interfere with the regular course of the evolution, clinical evidence of the nature of the process is always partially concealed, and in extreme cases differentiation from other focal lesions may be quite impossible.

Abnormal lesions, or modified lesions, to use the term in the meaning of any clinical departure from type, may occur in old age, or as the result of long continued ill-health. In these conditions the skin shares in the general depression and may fail to react in the normal way to the presence of the inflammatory focus. The lesion in such cases is apt to be less prominent in the vesicular stage, to be flat, ill-defined, and sometimes irregular in contour. It may resemble rather closely the lesion of varicella. Lesions of similar characters may be seen in the severe toxic attack, scattered over the surface here and there amongst the much more evident purpuric lesions. The abnormal characters in these cases may be the result of the over-whelming toxæmia.

Important Abnormalities in the Lesion.

The most important abnormalities in the lesion are the result of the existence in the patient of a degree of protection, natural or acquired, against the disease. A partial immunity, to use a convenient term, has a two-fold effect on the focal rash. The decrease which it usually brings about in the number of the lesions is the less important because it involves no interference with the clinical evidence of the nature of the inflammatory process. The more important effect is the decrease in the severity of the inflammatory process, involving a general decrease in the size of the lesions, a greater variation in their size than is seen in the normal rash, and a general speeding up of the clinical changes which occur in the course of the evolution. The result is that the papule is usually smaller than the normal small-pox papule, the vesicle and pustule do not involve the whole papule, and if the immunity is of high degree, the appearance of a small crust set on the top of a hypertrophied papule, in two or three days after the beginning of the outcrop of the rash, may be the only evidence available that vesiculation and pustulation have taken place in the lesion. That is to say, the clinical evidence of the nature of the process may be almost completely destroyed. The speeding up of the changes of evolution may become evident at any stage of the process, and in some lesions a true abortion of the process from the papular stage may occur. It is true that in the majority of cases of modified small-pox a proportion of the lesions will be found to conform more closely to type, but in a rash of very low numerical value it may be impossible to find reliable evidence of a deep-seated vesicle formation in any of its lesions at any time. The most valuable differential feature of the lesion, the unit of the rash, is not found in any of its anatomical characters, but in the fact that the process of evolution, even in the normal lesion, is regular and continuous and rapid. Appearances change from day to day and almost from hour to hour in the typical lesion, and only a very short period is required to demonstrate this feature, which has the additional advantage that it is not concealed but rather emphasised by the increased speed of the evolution under the influence of a partial immunity.

Differential Value of Distribution of Small-pox Rash.

Ricketts's researches and his demonstration of the supreme differential value of the features of the small-pox distribution are founded upon two independent observations which had been made several years before he began his work.

(*a*) It had been observed that the rash of natural small-pox has a tendency to affect the face and extremities in preference to the trunk; that on the trunk it is usually more densely set on the upper than on the lower parts, tending to avoid the lower part of the abdominal wall, and particularly the groin, the site of election of the petechial lesions; also that on the extremities the rash prefers the distal to the proximal parts—that is to say, the rash of small-pox is centrifugal rather than centripetal.

(*b*) It had also been observed that the lesions of the focal rash tend to cluster on and around an area which has been subjected to pressure or to the irritation of a local application. Experiment had shown that the irritation, in order to produce this effect, must be in action before or during the incubation period, because when applied after the onset of the disease no increase in the incidence of the rash on the affected part was observed.

To the study of these "irritation patches" Ricketts applied the pathology of inflammation and formed the opinion that irritation brought about an increased incidence of the lesions on the affected part through the disturbance which it caused in the peripheral circulation of the part. It is unnecessary for our purpose further to discuss Ricketts's convincing theory of the origin of the lesion, but one may summarise the conclusions to which he was led by his observations and experiments on the quality of the "irritation" which is necessary or desirable, if one may so speak, in order that the effect on the incidence of the rash may be most obvious. This quality is not severity. Severe irritation, sufficiently severe in itself or by reason of the duration of its application, tends not to increase the incidence, but to have the opposite effect, if the disturbance of the circulation is carried beyond the earliest stages of the process of inflammation. The "irritation," which amounts to no more than a slight stimulation, of which the patient may be quite unconscious, more especially when constantly repeated with slight intermissions, produces a very obvious effect in increasing the incidence of the rash on the affected part. The disturbance brought about in the circulation may be said to amount to no more than an increase in the normal oscillation of the current through the part, and never reaches the later static phase.

If the incidence of the rash can be influenced in so marked a manner by irritation which may amount to no more than a slight stimulation, is it not possible that a similar influence may be at work in producing the well-recognised natural tendency of the lesions to select certain areas in preference to others? Are there any conditions common to those areas which are analogous to irritative conditions in their effect on the circulation? Ricketts's reply to these questions is best given in his own words: "The operative causes are manifold, but the most potent factors are exposure to air and friction with clothing, and to their efficacy every case of small-pox is a testimonial."

Results of Protection of Part from Exposure and Friction.

Ricketts completed his demonstration by showing that the actual protection of a part from exposure and friction caused a decrease in the incidence in comparison with the corresponding part which was left unprotected. He had noted in instances in which small-pox followed surgical operation on the extremities that the part of the limb which was covered by wool and bandage appeared to be less affected by the rash than the corresponding part on the other side of the body, and he demonstrated the same result by direct experiment and noted that it is necessary to apply the protection not later than the onset of the disease, in order that any result may be obtained. This conclusion corresponds to the conclusion reached by a former observer regarding the time of application of an irritant in order that an increased incidence of the rash may occur.

Therefore, the parts of the surface which by their position or by their contour are naturally protected from exposure and friction are the parts on which the incidence of the rash is less evident, and the more complete and continuous the protection is, the greater is the tendency for the rash to avoid the protected part. For example, the most constantly and completely protected parts of the surface are usually the fold of the groin and the depth of the axilla, and these are the parts which the focal rash most consistently avoids.

The distribution of the focal rash of small-pox is governed by two factors, exposure and protection. These factors are common to every member of the race. They are independent of the course of the disease, of the evolutionary changes which constitute the features of the lesion, and of the modification of these changes which is the result of a partial immunity. The features of the distribution begin to be established with the beginning of the outcrop, they are fully established when outcrop is completed, and they remain unchanged as long as the rash lasts. The natural disposition of the focal rash to the surface of the body is modified only by individual peculiarities of habit and environment, and these local modifications of incidence are not usually difficult to interpret, and are more apt to assist than to hinder the recognition of the disease.

The Significance of Variation in Type of Infection in Small-pox.

The nature of an infection which has flourished almost continuously during recent years in many parts of the country has aroused considerable discussion, and suggestions have been made that the disease differs from normal small-pox and chicken-pox to an extent sufficient to justify the belief that it is a distinct disease, perhaps intermediate in character between small-pox and chicken-pox, or perhaps a hybrid, a varioloid varicella, or that it is a fixed variant of small-pox. In support of these suggestions attention has been directed to the almost complete absence of fatality, notwithstanding a high proportion of unvaccinated individuals among the patients, and also to the occurrence in unvaccinated patients of eruptions abnormal in character and therefore suggestive of the presence of a considerable degree of protection against the disease.

There is no doubt that a number of cases have occurred, and continue to occur, in the same districts where these abnormalities have been noted, in which the course of the disease and the features of the distribution of the rash, as well as the features of the lesions in their evolution, cannot be distinguished from the conditions recognised as typical small-pox. It is to be noted also that the abnormal conditions which have been emphasised concern the less important features of the evolution of the lesion and do not refer to the more important features of the distribution of the rash. There is also no apparent doubt that the relationship between many of the cases and vaccinia is identical with the relationship between vaccinia and small-pox. The very low rate of fatality or the complete absence of fatality cannot be used as an argument against the opinion that the disease is true small-pox. Great variation in fatality-rates is a well-recognised feature of epidemics. This variation has its value in indicating variation in type of disease, but has no value in differentiating one disease from another. It has an epidemiological and not a clinical significance.

There appears to be no doubt that small-pox has existed in many parts of the country during recent years, that it continues to flourish and to spread and has now become endemic in several districts. Fortunately, it is a mild type of the infection, and only in this respect may be regarded as a variant of small-pox. Whether it is a fixed variant or may at some time assume the features of the more virulent disease is a question on which it is advisable to reserve an opinion. *(To be concluded.)*

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Inspectors of the Local Government Department.

RECENTLY, in response to demands made in the Dail, the Government made a return showing the numbers of inspectors employed by the Local Government Department in 1914, in 1920, and in 1923, with the salaries paid. Although the area under the control of the Department has been diminished by six counties since 1914, the number of inspectors has increased from 8 medical and 28 lay in 1914 to 9 medical and 29 lay last year. At present the medical inspectors are paid salaries as follows: five receive from £500 to £700 a year with bonus, one £500 with bonus, one £420 to £600 with bonus, and two £700 inclusive. Of the 29 lay inspectors no less than nine receive either as much as, or more than, the most highly-paid medical inspectors. Of these nine, six get £500 to £700 with bonus, one £700 to £800 with bonus, one £700 to £900 with bonus, and one £1000 with bonus. It is not easy to see why the lay inspectors should be more highly paid than the medical. A medical inspector has undergone a long and arduous training before qualification, and has probably spent several years in the practice of his profession before being appointed to an inspectorship. A professional inspector should, therefore, receive higher remuneration than another. Some of the inspectors classed as lay are, no doubt, engineers, and therefore entitled to whatever advantages a professional status brings with it, but there seems to be no reason why engineering inspectors should be better paid than their medical colleagues.

The Free State Army Medical Service.

Major-General F. Morrin, who succeeded Major-General Hayes nearly a year ago as head of the Medical Service of the Free State Army, has now retired. General Morrin, who had previously served in the Royal Army Medical Corps, has been in the Medical Service of the Free State Army since it was founded nearly two years ago, and until his appointment last April as Director of the Service he was operating surgeon at the Curragh. He now returns to civil life and to his duties as one of the assistant surgeons to St. Vincent's Hospital. He was entertained to dinner last week, on his retirement, by the officers of the Medical Service, who made him a presentation in token of their appreciation of his conduct as head of the Service. In addition to the medical officers present, General Mulcahy (Minister of Defence), General M'Mahon (Chief of Staff), General O'Sullivan (Adjutant-General), and other officers holding high command attended and took part in the proceedings. The country is much in debt to both General Hayes and General Morrin for the work they have done for the Army under great difficulties and to the sacrifice of their private interests. The new head of the Medical Service is Colonel T. Higgins, who has been in the Service since its foundation, and previously served in the Royal Army Medical Corps.

University of Dublin.

The Senate of the University of Dublin has approved for the Honorary Degree of Doctor in Medicine the name of Surgeon Vice-Admiral Joseph Chambers, Medical Director-General of the British Navy. Admiral Chambers is a graduate of Dublin, and the first of that University to reach the highest medical post in the Navy. The Royal College of Physicians of Ireland recently elected him to an Honorary Fellowship.

RETIREMENT OF PROF. HILL ABRAM. — Prof. John Hill Abram, who for over 40 years has been connected with the Medical School of the University of Liverpool as student, lecturer, and professor, has just retired from the Chair of Medicine which he has held for the last two years. Prof. Abram has also given up his appointment on the staff of the Royal Infirmary, where for over 20 years he has been senior honorary physician. He will, however, continue in private practice. During his long association with the Medical School, Prof. Abram has been successively medical registrar, lecturer on pathology and clinical medicine, professor of therapeutics for 14 years, and he was appointed professor of medicine in 1922. On March 7th the students presented him in the Surgery Theatre of the University with a water-colour as a token of their appreciation, admiration, and affection. A humorous touch was added to the proceedings, when in addition to the picture there was handed to the professor a rather forbidding birch rod, which was described as "The Insignia of the Order of the Birch, presented for conspicuous merit in the application of the Art over an extensive period."

Correspondence.

"Audi alteram partem."

PREPARING HANDS AND GLOVES FOR OPERATION.

To the Editor of THE LANCET.

SIR,—Both Dr. G. W. Theobald and I wish to thank you for the kind and also amusing leading article which you devoted to our communication in the last issue of THE LANCET. We feel, however, that some of your criticisms should be answered, but since these were directed chiefly to the question of the bacteriological technique involved I, as the one responsible for that technique, am replying.

You state: "It is an essential part of the method that some reliance is placed on antiseptics and in particular on 1/1000 biniodide of mercury." What you were good enough to publish was merely an abstract, but in the complete communication Dr. Theobald dealt with the question of the antiseptic, pointed out that any disinfectant in any strength might be employed, and suggested that, if desired, concentrated sulphuric acid might be used. Even if your criticism of 1/1000 biniodide was entirely justified the method can still stand, as the use of biniodide 1/1000 is in no way fundamental. That solution was adopted chiefly because it was the one previously in common use for the preparation of hands in the Rotunda Hospital.

Again you state: "We must for the present feel a certain hesitation in accepting, sine grano salis, the statement made that gloves infected with virulent pus can be sterilised by mechanical washing and the use of dilute antiseptics." May I venture to offer the necessary grain of salt in the hope that it will make our contention sufficiently palatable for you to swallow? In one case a glove was contaminated with pus, blood, fæces, &c.; in the other it was covered with a culture of *B. coli*, which culture was made in a medium containing equal parts of broth and hydrocele fluid. In the second case the glove was dried before it was treated by Dr. Theobald's method, and it is believed that the conditions obtaining on it were exactly comparable to those on a glove contaminated with pus and other body fluids and then allowed to dry. When examined the gloves appeared to be sterile. This could only have been due to one or other of two things:—

1. All the bacteria had been removed or destroyed and the gloves were sterile.

2. An error had been made; the bacteria were still present and living but could not grow.

You appear to incline to the second view and in support of it you say: "Now, recent work has shown that, in general, mercurial solutions merely prevent growth and do not destroy bacteria," and you suggest that sodium thiosulphate should have been used to render inert any biniodide remaining. I am well aware, as is every bacteriologist who has performed tests of the germicidal power of disinfectants, of the danger of confusing inhibition of growth with actual destruction of bacteria. So far is this from being recent that it was realised many years ago when the "thread" method of testing germicidal power was in use, for ammonium sulphide or hydrogen sulphide was employed to render inert all traces of mercurial antiseptics before cultures were made. Such precautions were not considered necessary in our experiments because the gloves after treatment with biniodide were held under a stream of sterile water to remove all traces of that substance. I regret that this was not stated in our abstract, but our consideration for your valuable space led us to omit much which we should have liked to include. Supposing, however, that the disinfectant had not been removed, what would have been the concentration of biniodide in the cultures? It is just conceivable that as much as 0·5 c.cm. of the 1/1000 biniodide might remain on the glove if the washing had been omitted. This would be diluted 1/20 in saline and of this dilution 1·0 c.cm. would be added to about 15 c.cm. of agar. In the agar culture, therefore, the concentration of biniodide would be—$1/20 \times 1/15 \times 1/1000 = 1/300{,}000$. In the experiments made on the hands in gloves containing biniodide solution, the precaution of washing the hands before examination was not taken and yet, in one case, where the examined hand was tested while still wet with what had, originally at least, been 1/1000 biniodide, 14,700 bacteria were found to be present.

I realise that the question of inhibition is serious, and when I read your leader it struck me, as at least possible, that you were right and I was wrong. Since mere opinion must give place to definite evidence, I performed an experiment on Saturday to discover what concentration of biniodide would have an inhibiting effect under conditions similar to those prevailing in my tests. Various dilutions of biniodide in water were made and amounts of these were added to tubes of agar melted and cooled to 50° C., so as to give a series of tubes of agar containing biniodide in concentrations ranging from 1/10,000 to 1/500,000; two additional tubes received a similar amount of sterile water to act as controls. Two laboratory (not social) hands were scrubbed in sterile saline (20 c.cm.) and plates were made from the series of agar tubes, 1·0 c.cm. of the washings being added to each. To-day I have counted the colonies in the plates and the results are as follows:—

Agar with—	Colonies.	Agar with—	Colonies.
1/10,000 biniodide	0	1/250,000 biniodide	2330
1/25,000 ,,	0	1/300,000 ,,	2900
1/50,000 ,,	0	1/400,000 ,,	2680
1/75,000 ,,	0	1/500,000 ,,	2220
1/100,000 ,,	0	Agar without biniodide	2780
1/150,000 ,,	0	,, ,, ,,	2490
1/200,000 ,,	2180		

Despite the fact that the hands of the laboratory worker examined were too heavily contaminated with bacteria to give quite satisfactory plates, it is clear that under the conditions of my original tests, a smaller concentration of biniodide than 1/200,000 does not cause any serious inhibition of growth, and I claim that the method of testing employed was valid and, as a natural conclusion, that Dr. Theobald is justified in his contention that his treatment does sterilise "gloves infected with virulent pus." The bacteria were either removed or destroyed, and not merely anæsthetised.

I apologise for the length of this letter, but feared that condensation might only lead to further misinterpretation.—I am, Sir, yours faithfully,

JOSEPH W. BIGGER.

School of Pathology, Trinity College, Dublin, March 10th.

PETROL FOR SURGICAL SKIN TOILETTE.

To the Editor of THE LANCET.

SIR,—May I through your columns call attention to the use of petrol as an efficient substitute for ether in cleansing the skin for operation purposes? I have used this substance for this purpose for over 12 years with entirely satisfactory results. While at home recently I found that ether soap was the material used for this purpose at my old hospital (the London) and no doubt at other hospitals in the Kingdom. The amount of money annually expended in this way must be very great. I take absorbent cotton-wool as it comes from the manufacturer, wet it with petrol and scrub the skin with successive swabs until they come off clean. I then paint the skin with tr. iodi made from methylated spirit and cover with a sterilised towel. This is done the night before and repeated again on the operating table. I find that petrol is quite as efficient as ether in the extraction of fat and dirt from the skin, thus allowing the iodine to penetrate. I use ordinary petrol and my results are quite as good as they were in the days when I used ether soap.—I am, Sir, yours faithfully,

F. J. W. PORTER,
Major, R.A.M.C. (retd.)

Surgical Nursing Home, Bombay, Feb. 12th, 1924.

TESTS FOR CURE OF GONORRHŒA IN WOMEN.

To the Editor of THE LANCET.

SIR,—In your issue of March 1st Mr. J. J. Abraham rates the value of cultures in the examination of women with gonorrhœa so low as "useless" when compared with films. His experiences, however, are somewhat unusual. Using hydrocele agar or serum agar, overgrowth by other organisms is seldom of consequence in the female, and, as is to be expected, more "positives" are obtained by culture than by film :—

Cultures and films from women	220
Positive by culture	53
„ „ film..	42

Furthermore, the culture method is safer, because the worker has both morphological *and* cultural characters to aid him. Indeed, the value of cultures over films in women is considered so marked here that, by arrangement with Mr. Hugh Lett and Dr. A. M. Simpson, routine films have been dispensed with, and cultures are taken by the staff in the women's clinic.—We are, Sir, yours faithfully,

PAUL FILDES.
London Hospital, E., March 6th, 1924. G. T. WESTERN.

CERTIFICATES OF INSANITY.

To the Editor of THE LANCET.

SIR,—I trust that you will lend your influential aid in endeavouring to relieve the profession from the risks that it unnecessarily runs in signing the present certificates of insanity. The legislature demands that a person suffering from dangerous insanity should be deprived of his liberty, and it is the duty of the legislature to provide that the detention is necessary and right. A non-official general practitioner is not the servant of the legislature, and should therefore not be required to take any responsible part in carrying out its objects; his duty only consists in advising the treatment necessary. If he voluntarily undertakes to aid the legislature by giving an opinion, with the facts on which that opinion is based, he should not be held responsible for the action that the legislature takes upon that opinion and testimony, and the certificate should be framed in accordance with this principle.

I therefore suggest that after paragraph 5 in the medical certificate of insanity form some addition should be made to the effect that, since the facts stated may reveal secrets obtained professionally, the certificate should be regarded as privileged and should not be revealed, in any way that could lead to the injury of the signer, legally or otherwise. I suggest that the whole profession should unite to obtain this protection from the legislature, or alternatively decline to sign certificates in the present form.

I am, Sir, yours faithfully,
March 5th, 1924. H. RAYNER.

CHOLESTEROL AND TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I am anxious to know whether any serious trial has been made of cholesterol as a therapeutic adjuvant in cases of tuberculosis, especially pulmonary tuberculosis—either by methodically increasing the cholesterol-intake in the diet or by other medicinal methods. In the careful résumé of hitherto tried treatment given by Dr. R. A. Young in his second Lettsomian lecture, on March 5th, no mention of cholesterol was made. Perhaps readers of THE LANCET can inform me on the subject. A high cholesterol-content in the blood is supposed by some to indicate good resistance towards bacterial infections, and it is remarkable that in diseases often associated with hypercholesterinæmia—gout, arterial atheroma, arteriosclerosis, chronic interstitial nephritis, and chronic cholelithiasis—there seems to be considerable antagonism towards acute pulmonary tuberculosis. Diabetes mellitus, though often associated with hypercholesterinæmia, should be placed on one side, as apparently the hyperglycæmia and wasting favour pulmonary tuberculosis. It would also be interesting to know whether methodical reduction of the cholesterol in-take in the diet can diminish the liability to arterial atheroma, &c. The experimental production of aortic atheroma in rabbits by cholesterol-feeding can hardly be taken as strong evidence, since rabbits are peculiarly liable to atheroma.

I am, Sir, yours faithfully,
London, W., March 6th, 1924. F. PARKES WEBER.

INHALATION IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In his second Lettsomian lecture on the treatment of pulmonary tuberculosis, reported in your last issue, Dr. R. A. Young has given a place to inhalations in his survey of various methods of treatment. I have been using inhalation in conjunction with sanatorium treatment for the last 25 years with considerable benefit. The mixture I am in favour of is one containing guaiacol, terebene, menthol, ol. pin. pumil., chloroform, and rectified spirit with or without tinct. iodine or formalin (2½ to 5 per cent.), which is manufactured by Oppenheimer, Son, and Co., London. The inhalation relieves the patient's cough, determines more blood to his lungs like Kuhn's mask, protects him from strong winds and dust, and prevents any infectious cold or catarrh of the nose and throat from spreading downwards and starting fresh mischief in the lungs, and thus in many ways it helps to arrest the disease. Its results are striking when it is used continuously and perseveringly.

I am, Sir, yours faithfully,
Mendip Hills Sanatorium, March 10th, 1924. C. MUTHU.

THE POSITION OF NON-PANEL PRACTICE.

To the Editor of THE LANCET.

SIR,—The National Medical Union of Non-panel Medical Practitioners is accumulating evidence to lay before the approaching Royal Commission. As the whole system of panel medical practice is to come under review, it is very important that the non-panel case should be adequately presented.

With a view to assisting the Royal Commission to come to a clear decision on the merits of the Medical Benefit Section of the National Health Insurance Acts, all insured persons are requested earnestly to reply to the two following questions :—

A. Are you satisfied with the present panel medical system ?

Answer .....

B. If not, would you prefer to make your own arrangements for medical attendance, receiving when sick a certain amount of money towards your medical expenses, and consulting the doctor of your choice ?

Answer .....

I am, Sir, yours faithfully,
E. H. WORTH, M.R.C.S.
(for the Hon. Secs., N.M.U.).
11, Chandos-street, Cavendish-square, W., March 5th.

STAPLE HOLDERS FOR ROUX'S OPERATION.

To the Editor of THE LANCET.

SIR,—In your issue for March 1st (p. 465) Mr. C. M. Page's staple holder is shown. I was not aware of his invention, which resembles in idea my own. Mr. Page's staple holder is for the Roux staple, and unless altered it would be useless to take the Jacöel. I think the advantage of my staple holder over that of Mr. Page is that the sides of the staple are in no way obscured by the holder.

I am, Sir, yours faithfully,
Glasgow, March 5th, 1924. A. MACLENNAN.

A "GRADED FACTORY" FOR TUBERCULOUS PATIENTS AND EX-PATIENTS.

To the Editor of THE LANCET.

SIR,—I have had my attention drawn to a statement I made in my article with this title. I wrote: "Some sanatoria are self-supporting and even make a profit." I should be glad to correct this statement so that it may run: "Some sanatoria are maintained well under their estimates and thereby have a good balance in hand."

I am, Sir, yours faithfully,

CHARLES F. PEDLEY.

Winsley Sanatorium, nr. Bath, March 3rd, 1924.

POST-OPERATIVE INSANITY.

To the Editor of THE LANCET.

SIR,—The case described by Dr. A. J. Cokkinis in your issue of March 8th is of great interest. His suggestion that his patient's unfortunate condition is due to minute focal hæmorrhages or thromboses destroying certain association fibres in the silent areas of the brain is probably the correct solution. At the same time it is doubtful whether a resection of the nasal septum is justifiable in elderly patients, save, possibly, under exceptional circumstances. In the majority of persons over fifty I am always chary of advising such operations. An experience of over a thousand has taught me that the rapidity of recovery varies in direct proportion with the age of the patient.

I am, Sir, yours faithfully,

MACLEOD YEARSLEY.

Wimpole-street, W., March 8th, 1924.

ITALIAN LABELS ON PROPRIETARY MEDICINES.

To the Editor of THE LANCET.

SIR,—Our attention has been called to an article entitled, Secret Remedies: Formulas Disclosed by the Makers, published in your issue of Feb. 2nd. These formulas have apparently been obtained from Italian sources. Among them is found one for "Collis Browne's Chlorodyne." As the headlines and the introductory paragraph of your article suggest that these formulas are given by the makers themselves, we beg to inform you that we have never "disclosed" our formula.

From a recent experience of our own we are led to suggest that you have been misled. An order for Dr. J. Collis Browne's Chlorodyne was placed with us by an Italian firm. Accompanying it came a parcel of small labels bearing a formula which the firm requested us to attach to our bottles. We refused. Surprise was then expressed at our refusal "*as the formula-label was only required for preferential Customs Tariff purposes.*" We send a specimen for your information. You will note that it is different again from the one which you publish.

> Cloroformio Puro 6.00, Est. Liquorizia Acquoso 12.00, Cloridrato di Morfina 0.15, Essenza di Menta 0.10, Miele depurato 25.00, Sciroppo Semplice q. b. per fare 100.00.

It is evident that certain Italians must be affixing anything they like to proprietaries imported into or sold in Italy by them without consulting the makers.

We are, Sir, yours faithfully,

J. T. DAVENPORT, LTD.

London, March 10th, 1924.

THE PEOPLE'S LEAGUE OF HEALTH.—Prof. J. C. Drummond will deliver the fifth lecture of the Sims Woodhead series of Constructive Educational Health lectures, which the People's League of Health is giving at the Medical Society of London, 11, Chandos-street, Cavendish-square, W. 1, on March 10th, at 6 P.M., the subject being Food. Further particulars can be obtained from Miss Olga Nethersole, the People's League of Health, 12, Stratford-place, W. 1.

Obituary.

ANN ELIZABETH CLARK, M.D.BERNE, M.R.C.P.I.

THE death of Dr. Annie Clark on Feb. 25th in her eightieth year removes one of the few remaining pioneers of women in medicine. Her death occurred at Street, Somerset, whither she had returned on retiring from active practice in 1914.

Ann Elizabeth Clark was born at Street in September, 1844, the seventh of the 14 children of James and Eleanor Clark (née Stephens). Privately educated at Laura-place, Bath, it was not until late in her twenties that she began to study for university entrance. Joining Sophia Jex-Blake, Agnes McLaren, and Edith Pechey at Edinburgh, she moved to London in 1874 when women students were excluded

DR. ANNIE CLARK.

from Edinburgh, and obtained a medical degree in 1877 after two years' study at Berne, where Theodore Kocher was a good friend to her. A year later the Royal College of Physicians of Ireland admitted her as a licentiate, and after further study in Paris, Vienna, and Boston, she went to Birmingham in 1878 as resident medical officer to the Midland Hospital for Women, later becoming the first woman on its honorary staff. She was also for more than 20 years on the staff of the Children's Hospital.

In Birmingham Dr. Annie Clark soon built up a large private practice, notably among poor people. Not richly endowed with the gifts and graces which make it easy to gain popularity in social life, she had a sure instinct for what was possible and practicable in any given household. "She always seemed to know exactly what to do," her patients said of her, and she was sometimes criticised for allowing herself to become exhausted through sympathy for those to whom she ministered. At the Women's Hospital she was associated in succession with Mr. Lawson Tait, Mr. J. W. Taylor, and Mr. Frederick Edge—not having the F.R.C.S. she did not operate herself in the hospital—and the last-named writes thus of her:—

> "For anyone who had not worked with Dr. Annie Clark it would be difficult to believe that such a quiet little oldish woman doctor could have had the strong kindly influence over her colleagues which she always exerted. There were

men of strong character about her and working with her, but it is no exaggeration to state that not one of her colleagues influenced the tone and standard of the hospital more than she did. In life it comes as a revelation to see how much a noble mind, conscious of right, can effect, and how little it counts whether that mind be in a body of slight form or in a massive frame. In this instance we had a gentle, retiring woman with a great tolerant understanding, beloved by all who knew her. Whatever happened in the way of blunder, or neglect, or unworthy practice, meriting and perhaps receiving blame from others, nothing but sympathy and wise counsel came from her. At a time when there was among medical men much suspicion and some mild fear of medical women, which to some slight degree may have been justified by the advertisement and publicity given by the lay press to anything connected with women entering the profession, it was like a soothing balsam to know and work with this fine example of what a medical woman could be."

As one of the senior members on the staff of the Children's Hospital she was ever ready to discuss new methods and ideas with her juniors, seeking how to bring the results of investigations, which they had more time than she to carry out, to the service of the patients. One of the juniors writes of her aptitude for seeing the practical bearing of pathology and bacteriology in her ward work, adding: "Dr. Clark was ready generously to acknowledge any assistance thus given her by even the youngest member of the staff. There was a quiet happiness about her that won the regard of those associated with her." Her habit of speaking the truth without evasion was carried far beyond what is usual in every-day life. If a patient asked a question to which the answer was painful she believed it right always to tell the truth, holding that the sick person had a right to this straight dealing. From the first she refused to order alcohol for her patients. She demanded the best of people on account of believing the best of them. Her patients had a sense of her devotion to their interests, and when she left Birmingham they raised a sum of £750 to endow a bed at the home for cancer cases started by her and a few colleagues.

After retiring to Street, where she lived with a younger sister, Dr. Annie Clark was able to enjoy more fully her absorbing hobbies of travel, botany, and archæology. Her advice was still available at the local baby clinic, and she acted for some time as hon. secretary of the Belgian Committee. As she became physically more invalid her interest in life never flagged. Her last illness was of only a week's duration. Her body was cremated at Birmingham on Feb. 29th, and the ashes laid in the Friends' Burial Ground at Street.

HENRY ALEXIS THOMSON, F.R.C.S. ED. & ENG.

BY the death of Emeritus Prof. Alexis Thomson at Algeciras in his sixty-first year, on March 4th, there passes from the Edinburgh Medical School one of its most prominent and popular figures. Last October Prof. Thomson formally retired from the chair of systematic surgery in Edinburgh University, which he had held for the past 14 years, as ill-health prohibited further professional duties.

Prof. Thomson, one of the seven sons of an eminent Edinburgh business man, was born in Edinburgh in 1863, and passed his schooldays at the Royal High School there. Before taking up the study of medicine he spent two years at the Realhochschule of Hanover, and in France, where he acquired an intimate knowledge of French and German. At the University of Edinburgh he distinguished himself among his fellow medical students, gaining medals in both systematic and clinical surgery, and graduating with honours in 1885 at the age of 22. In the same year he became a Member of the Royal College of Surgeons of England, of which body, many years later, he was elected a Fellow.

After graduation he acted as house surgeon in the Sick Children's Hospital and in the Royal Infirmary under Mr. John Duncan, whose clinical tutor and private assistant he afterwards became. After a few months' experience in general practice he commenced practice as a surgeon in 1887, and in the following year was elected a Fellow of the Royal College of Surgeons of Edinburgh. At this time, along with Mr. Harold Stiles, he ran a most successful coaching class in anatomy and pathology for the second professional examination. He was one of the earliest workers in the College of Physicians laboratory when this was in Lauriston-lane, and it was here that he did a great deal of the work for his M.D. thesis on Tuberculosis of Bones and Joints, for which he received a gold medal five years after graduation, and was appointed joint holder of the Freeland-Barbour Fellowship by the Royal College of Physicians. He acted for a time as assistant to Prof. Greenfield, and to this experience, no doubt, was due in part his keen and sustained interest in surgical pathology. In 1888 he became a B.Sc. in public health. About this time he started lecturing on surgery in Minto House, where he was associated with Symington. In 1892 he was appointed assistant surgeon to the Royal Infirmary, and two years later surgeon to the newly opened Deaconess Hospital. On the retiral of Prof. Chiene in 1909, he was appointed, after a close contest with Mr. James Hodsdon, to the vacant chair of systematic surgery.

During his years of professorship there were few students who attended his morning lectures who did not feel the spell of his personality and his refreshing vigour. He had a naturally attractive voice and never at a loss for a word, he presented his subject with a racy force that appealed to the imagination and aided the memory, while his skill with instance and illustration constantly added a lighter touch. His lectures were always carefully prepared, but he could lecture at a moment's notice, presenting his subject as fluently and as carefully as if there had been time for the usual preparation. In addition to the spoken word, he made a point of illustrating his lectures by demonstrations, and was one of the first to introduce the epidiascope, and later was probably the first surgeon in this country to employ the cinematograph for teaching purposes. In this way rare cases and exceptional operations could be demonstrated to his lecture class by films made under his own supervision. His interest in the students was not confined to their work, for he was an enthusiastic supporter of the athletic club and followed its activities keenly. He delighted to entertain a number of students or residents from the infirmary at his country house in Gilmerton when the felling of trees and the sawing of logs formed an integral part of the programme along with tennis or croquet. He himself was a keen sportsman, golf, shooting, fishing, and bicycling claiming in him a devotee. As an operator he was skilful and daring. He was at his best in difficult and dangerous cases, and his results were often brilliant. He had a *flair* for diagnosis, his gift at times being almost uncanny. In the technique and organisation of surgery he was one of the first to recognise the great progress which had developed in America, and he did much to incorporate in his own practice the improvements and methods observed on his many visits to American clinics, where he was always an honoured visitor.

Much of Prof. Thomson's reputation was due to the valuable contributions he made to medical literature. His original writings covered a wide part of the field of modern surgery. One of his best known contributions was a monograph on Neuroma and Neurofibromatosis, which was published in 1900, and later was translated into French. He wrote frequently for the medical journals, and especially in the *Edinburgh Medical Journal*, of which he was joint editor for several years. With his colleague, Mr. Alexander Miles, he published in 1904 a manual of surgery, in two volumes. Since then the manual has passed through numerous editions, and has been extended to four volumes. This text-book has been recognised as one of the best in the English language. Prof. Thomson was a member of Council of the Royal

College of Surgeons of Edinburgh, and frequently represented the College at medical congresses abroad; but for his health he would have succeeded to the Presidency of the College in the year of his retirement. He was consulting surgeon to the Royal Infirmary and to the Deaconess Hospital, and enjoyed honorary membership of the French Association of Surgeons and of the American Society of Clinical Surgery, and an Honorary Fellowship of the American Surgical Association. During the war he acted as consulting surgeon to the Third Army of the British Expeditionary Force, and for his services was awarded the C.M.G.

Prof. Thomson was buried at Gibraltar, and is survived by his wife.

GUY ALFRED WYON, M.D. EDIN.

Dr. G. A. Wyon, lecturer in pathology at the University of Leeds, died on March 2nd, in his fortieth year, after a short illness of influenzal character.

Guy Alfred Wyon was a son of Allan Wyon, F.S.A., the medallist, who belonged to the family of engravers of that name so long associated with the Mint. He was born in Hampstead in 1885, went to school at Highgate, and then graduated B.Sc. at London University. He received his medical education at Edinburgh University, qualifying M.B., Ch.B. in 1910, and there five years later he obtained his M.D. After some experience as house surgeon and house physician at the East Suffolk and Ipswich Hospital, and later as a general practitioner in the East End of London, Dr. Wyon joined the R.A.M.C. in 1915 and was sent to Salonika. On returning from that theatre of war, however, the strong bent of his mind for medical work of a scientific character asserted itself, and under the Medical Research Committee he was associated with the late Prof. Benjamin Moore in some useful work on the causation and prevention of T.N.T. poisoning, which is described in the M.R.C. Report, No. 58. He spent the latter part of the war in France attached to the 13th Casualty Clearing Station, and was busy with researches in all the quieter periods. These he carried out in the different mobile laboratories which were attached to the Casualty Clearing Station. About the time of the Armistice he took charge of No. 16 Mobile Laboratory and worked in the neighbourhood of Namur until demobilised.

Dr. Wyon joined the department of pathology at Leeds University in December, 1919, and occupied the position of lecturer in that department at the time of his death. While at Leeds he published some interesting work on bacterial nutrition, with special reference to the significance of amino-acids and vitamins. Tall in stature and possessed of an unusual gentleness of character, Wyon was an arresting personality and he had won a special place for himself in the hearts of many at the University of Leeds which will not easily be filled. As a worker he had two specially marked characteristics: one was his anxiety to get at the fundamental aspects of all problems which he tackled, and the other his enthusiasm and alacrity in bringing new methods to bear on his work. The contribution which he made to progress in the centre in which he worked was much greater than can be gauged by his published work alone. He is survived by his widow, formerly Miss Hitchcock, of Bures, Suffolk, and three children.

THE LATE DR. CLEMENT HADLEY.—The death is announced of Dr. Clement Hadley, second son of the late John Joseph Hadley, M.R.C.S., of Birmingham, at Leicester on March 11th, in his seventy-ninth year. Dr. Hadley qualified M.R.C.S. Eng. 1871, and L.R.C.P.I. & L.M. 1880, and subsequently practised at Ashted-row, Birmingham, for over 30 years, and at Shilton, near Coventry, for 14 years. He leaves a widow and two sons and two daughters.

UNIVERSITY OF LIVERPOOL.—Dr. John Hay, senior hon. physician to the Royal Infirmary, has been appointed Professor of Medicine at the University.

Medical News.

UNIVERSITY OF CAMBRIDGE: *The John Lucas Walker Studentship.*—Applications for this studentship, the holder of which shall devote himself (or herself) to original research in pathology, are invited, and should be sent, accompanied by copies of papers containing published work, testimonials, and references, before May 1st next, to Prof. H. R. Dean, Pathological Laboratory, Medical School, Cambridge, to whom also applications for further information regarding the studentship may be addressed. The studentship is of the annual value of £300, and is tenable, under certain conditions, for three years from May 31st, 1924.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The usual list of Fellows, Members, and extra-licentiate has just been issued, this time separately from that of licentiates and diplomates in special subjects; 14 Fellows were admitted during the year 1923, the total number now being 374. The senior Fellows are: (1870) Sir William Selby Church and Sir Dyce Duckworth, (1873) Sir Richard Douglas Powell, (1874) Dr. Henry Gervis and Dr. John Buckley Bradbury, (1876) Sir David Ferrier, (1877) Dr. Michael Grabham, (1878) Dr. J. Mitchell Bruce and Dr. C. G. H. Bäumler, (1879) Sir John Williams. Fifty-nine Members were admitted during the year, the total number now being 636. The senior Members are: (1860) Dr. Clarence Cooper, (1865) Dr. Heywood Smith, (1866) Dr. Francis V. Paxton.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A meeting of Fellows will be held at the College on July 3rd for the election of three Fellows into the Council in the vacancies occasioned by rotational retirement. The occasion will mark an innovation, for a reception will be held by the President and Council from 4 to 6 P.M. on the same day, and the annual exhibition of additions to the museum will be open for inspection at that time. Formerly, when Fellows had to attend at the College to record their votes, the annual exhibition of additions to the museum was held on the day of the Council election, but in recent years the exhibition has been held in October. It is now proposed to revert to the custom of holding the exhibition on the same day as the Council election, and to hold a reception in connexion with it.

JOULE MEMORIAL LECTURE.—The third memorial Joule lecture was delivered on March 4th at the rooms of the Manchester Literary and Philosophical Society, by Prof. A. V. Hill, who took for his subject Thermodynamics in Physiology. He said that the guiding principles in the life and labour of Joule—those of precise measure and accurate definition—were the essential needs of physiology at the present time, and the hour would come when physiology would find its Einstein, its Maxwell, and its Laplace, but to-day it required a Joule—indeed, a dozen Joules—to carry out accurate measurements and to formulate precise definitions which were essential if it was to secure its promotion from the nursery of observation and wonder to the school-room of exact science.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A three weeks' course on Diseases of Children will be given at the Royal Waterloo Hospital for Children and Women from March 17th to April 5th. The various aspects of the subject will be dealt with by lecture-demonstrations, ward work, and out-patient clinics by the members of the staff according to the time-table set out in the syllabus. At the Royal Westminster Ophthalmic Hospital there will be a course on Ophthalmology from March 31st to April 17th, which will include clinical instruction every afternoon from 2 P.M., and special demonstrations twice a week on Medical Ophthalmology and Methods of Examination. At the London Temperance Hospital, Hampstead-road, there will be an intensive course from March 31st to April 12th. Practical demonstrations will be given each morning from 10.15 to 12.15, and the afternoons, from 2 to 4 P.M., will be devoted to ward rounds and out-patient clinics. In addition, special demonstrations will be given on Saturdays at Bethlem Royal Hospital on Mental Diseases, and on Ophthalmology at the Royal Westminster Ophthalmic Hospital. There will also be a lecture each day at 4.30 P.M., to which all members of the medical profession are invited, and the opening one will be given by Sir Humphry Rolleston on March 31st, followed among others, by Mr. V. Zachary Cope, Mr. Ernest Clarke, Dr. Soltau Fenwick, and Mr. W. Ernest Miles. Copies of the syllabus with full particulars can be obtained on application to the Secretary to the Fellowship of Medicine, 1, Wimpole-street, London, W. 1.

Mr. R. A. Bickersteth, F.R.C.S. Eng., honorary consulting surgeon to the Royal Infirmary, Liverpool, died at Bournemouth, on March 6th, in his sixty-second year.

HARVEIAN SOCIETY OF LONDON.—A meeting will will be held at Paddington Town Hall on March 20th, at 8.30 P.M., when Prof. J. Ernest Frazer will deliver the annual Harveian lecture.

CHELSEA CLINICAL SOCIETY.—A meeting of the Society will take place at St. George's Hospital on March 18th at 8.30 P.M., when a discussion on the Treatment of Common Eye Disorders will be opened by Dr. Ernest Clarke.

ELIZABETH GARRETT ANDERSON HOSPITAL.—The annual meeting of the hospital, Euston-road, N.W., will be held to-day, Friday, March 14th, at 3 P.M., under the chairmanship of Lord Riddell. Mrs. Fawcett will speak.

RADIUM INSTITUTE, LONDON.—With the approval of the King, Sir Anthony A. Bowlby has been elected Chairman of the Institute in place of the late Sir Malcolm Morris. Sir George Blacker has been elected a member of the Committee.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—The sixth meeting of the session will be held at the Miller General Hospital, Greenwich, to-day, Friday, March 14th, at 8.45 P.M., when a paper will be read by Dr. Montague L. Hine on the Interdependence of Ophthalmology and General Medicine.

HARNETT *v.* BOND AND ADAM: STAY OF EXECUTION.—In the King's Bench Division on March 11th Mr. Justice Lush granted Dr. G. H. Adam an extension of a stay of execution with regard to the damages awarded against him. This followed on an assurance given by counsel for the Crown that security would be given for the outstanding damages of £20,000 before March 21st. Extension was granted without any condition until the hearing of the appeal.

SOCIETY OF MEDICAL OFFICERS OF HEALTH: *Maternity and Child Welfare Group.*—A meeting of this group will be held in the house of the society, 1, Upper Montague-street, Russell-square, W.C., at 8 P.M., on March 20th. Dr. Robert Hutchison will read a paper, illustrated by lantern slides, on the Feeding of Children after the Period of Infancy. The lecture is open to all interested in maternity and child welfare work, and members of the dental and school medical groups are invited to attend.

THE JOURNAL OF LARYNGOLOGY, LIMITED.—The conductors of the *Journal of Laryngology* held their annual dinner on Friday, March 7th, at Pagani's Restaurant. Sir William Milligan presided, and gave the toast of The Prosperity of the Journal in a speech explaining the sound grounds on which those responsible believed that the progress already made was likely to continue. The editor of the *Journal*, Dr. Logan Turner, gave figures which showed that the journal was well supported, but had a right to count upon many more adherents. The toast of The Guests was replied to by Sir Charles Ballance and Sir Squire Sprigge, who bore testimony to the industry and accuracy which were required to make adequate abstracts of scientific communications.

INSURANCE FUNDS AND VOLUNTARY HOSPITALS.—In reply to the statement made by Lord Colwyn at the annual meeting of the Manchester Children's Hospital concerning the surplus funds of approved societies (THE LANCET, March 8th, p. 521), a letter has appeared in the press from Sir Thomas Neill, chairman of the National Amalgamated Society. Sir Thomas Neill states that it is true that the last valuation of approved societies disclosed a surplus of £17,000,000, but of this amount £8,000,000 was set aside by the Government Valuers as a reserve. The remaining £9,000,000 was declared disposable, and in accordance with the provisions of the National Insurance Acts was distributed by the various societies among their members in the form of certain benefits defined in the Acts—including dental, optical, and home convalescent treatment, the provision of medical and surgical appliances, and contributions to voluntary hospitals in respect of the treatment of insured persons. The Industrial Assurance Approved Societies, which adminster benefits to over six million insured persons out of a total of 15 million insured persons, has contributed over £174,000 to voluntary hospitals throughout the country, and Manchester institutions have received over £5400. It is the earnest hope of the approved societies that all available surplus shall be used to the utmost to support voluntary hospitals, because by doing this many wards and beds have been kept open which would otherwise have been closed down.

THE KING has sanctioned the following appointments to the Order of the Hospital of St. John of Jerusalem in England: Sir Gould May, Sir John Bland-Sutton, P.R.C.S., and Captain James Atkin Henton White, R.A.M.C., to be Knights of Grace; and Dr. Alfred Bakewell Howitt to be an Esquire.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of the Faculty on March 3rd Dr. James Duncan Maclaren was admitted as an Honorary Fellow, and Dr. Dattatraya Ganesh Kotibhaskar was admitted (after examination) as a Fellow.

DR. ROBERT HUNTER STEEN, medical superintendent of the City of London Mental Hospital, has resigned the post of professor of psychological medicine and out-patient physician for mental diseases at King's College Hospital, Denmark Hill, and the Council of King's College has conferred upon him the title of Emeritus Professor of Psychological Medicine.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—Hospitals in the County of London or within nine miles of Charing Cross, desiring to participate in the grants made by this Fund for the year 1924, should make application before March 31st to the hon. secretaries of the Fund at 7, Walbrook, London, E.C. 4. Applications will also be considered from convalescent homes which are situated within the above boundaries or which, being situated outside, take a large proportion of patients from London.

ENCEPHALITIS LETHARGICA IN ENGLAND AND WALES.—Cases of this infectious disease to the number of 86 were notified in England and Wales during the week ended March 1st, the numbers in preceding weeks (working backwards) being 61, 33, 37, 19, 18, 18, 10, 8, taking them back to the beginning of the year. Of the 86 cases the districts of notification were: County of London 3 (Bethnal Green, Fulham, Stepney); Cheshire 8 (Birkenhead 1, Stockport 2, urban districts 5); Cumberland, 1; Derby, 1; Dorset, 1; Durham, 2; Essex, 3; Kent, 1; Lancashire, 58 (Blackpool 1, Bolton 3, Bury 1, Liverpool 2, Manchester 22, Oldham 6, Rochdale 1, Salford 9, Ashton-under-Lyne 1, Eccles 1, Ince-in-Makerfield 1, Irlam 1, Middleton 1, Radcliffe 1, Swinton and Pendlebury 1, Tyldesley with Shakerley 1, Westhoughton 1, Whitefield 1, Whitworth 2, Worsley 1); Hants, 1 (Winchester); Surrey, 1; Sussex, 1; Warwick, 2 (Birmingham); Yorks, W.R., 2 (Halifax 1, Hemsworth 1); Glamorgan, 1. It will be seen that the adjacent counties of Lancaster and Chester account for all but 20 of the cases.

NORFOLK AND NORWICH HOSPITAL.—At a recent quarterly meeting of the governors of this hospital the report of the board of management showed that the number of in-patients admitted during the quarter had been 823, compared with 778 in the corresponding quarter of last year. The daily average of in-patients was 239, and the number of operations performed 739. The number of cases treated in the out-patient department had been 1079 (1084 last year), and the accidents and casualties 1767, as against 1520 last year. The board reported that they anticipated that the heating and hot-water supply from the new boiler-house would be connected up during the next few weeks, and that the extensions to the electrotherapeutic department, as well as the extensions and alterations to the laundry, were nearing completion. Mr. Donald Day, senior surgeon to the hospital, had retired, and was appointed a consulting surgeon. Mr. A. J. Blaxland was promoted to the post of honorary surgeon, and Mr. W. B. Bulman was appointed honorary assistant surgeon. A new arrangement had been made with regard to children operated on in the out-patient department for the removal of tonsils and adenoids. For the future these patients would be transported to their own homes in ambulances provided by the British Red Cross Society at a small charge. Mr. S. H. Barton, chairman of the board of management, in moving the adoption of the report, made special reference to the treatment of cases of diabetes by insulin, and stated that this hospital was one of the first to adopt this treatment. There had been as many as 14 such cases at one time under treatment, and the usual number was eight. Such specialised treatment as this created a demand for beds, but owing to the cost of insulin it threw a strain on the finances of the hospital. The ward which had been reserved for discharged soldiers was now available for civilian cases, as there were now only eight soldiers in the hospital, against 40 last year. This would throw an additional burden on the hospital finances, as there would be a loss in payments of over £1500, but the board felt that the civilian patients, and especially the members of the Contributory Scheme, who formed 70 per cent. of the number, would do all in their power to assist in making up the deficit.

NATIONAL BUREAU FOR PROMOTING THE GENERAL WELFARE OF THE DEAF.—Under the auspices of this Bureau an important conference of societies engaged in the promotion of the welfare of the deaf will be held at the Kingsway Hall, Kingsway, London, W.C., on March 19th, at 3 P.M., when Lord Charnwood will preside.

WELSH NATIONAL SCHOOL OF MEDICINE.—The Senate of the University of London has now recognised the final years of study held at the Cardiff Royal Infirmary as courses qualifying for the examinations of the University of London. Prof. Graham Brown has succeeded Prof. A. M. Kennedy as dean of the school.

MEDICO-LEGAL SOCIETY.—A meeting will be held at 11, Chandos-street, Cavendish-square, London, W. 1, on March 18th at 8.30 P.M., when notes will be read on Cases of Sudden Death from Inhibition and their Medico-Legal Bearings, by Dr. Percy B. Spurgin and Sir Bernard Spilsbury. Any members who can contribute notes of similar cases are requested to take part in the discussion.

DONATIONS AND BEQUESTS.—For the British Empire campaign the following donations have been received recently: £1000 from Mr. Jackson Russell, of Archerfield, Dirleton, East Lothian; £1111 collected by the County of London Branch, British Red Cross Society, including £1000 raised by the Holborn Division (Commandant, Miss Geering); and £200 from Mr. S. G. Asher, chairman of the council, Middlesex Hospital Medical School. A large number of anonymous gifts have also been received.

MAUDSLEY HOSPITAL.—The second part of the seventh course of lectures and practical courses of instruction for the diploma in psychological medicine will begin on March 31st. Lectures will be given by Dr. Bernard Hart, Dr. Edward Mapother, Sir Frederick Mott, Dr. C. Hubert Bond, Dr. F. C. Shrubsall, and Dr. W. C. Sullivan, and 12 clinical demonstrations in neurology will be given by Sir Frederick Mott and Dr. F. L. Golla. Further particulars will be sent on application to the director of the pathological laboratory at the hospital, Denmark Hill, London, S.E. 5.

THE INSULIN TREATMENT OF DIABETES IN SCOTLAND.—The Scottish Board of Health have had under consideration the position of Poor-law authorities in relation to the provision of insulin treatment for diabetic patients. In regard to persons actually on the roll of poor it is obviously the duty of the parish council to provide whatever medical treatment and medicines the medical officer considers necessary, and the Board do not anticipate that any parish council will raise difficulties in cases where the medical officer considers that insulin should be administered. There is a further class of patient in respect of whom the parish council may be called upon to consider an application for the provision of insulin treatment. That is the patient who is in possession of means which, according to normal Poor-law standards would be sufficient for his ordinary maintenance. Such means may not, however, be sufficient to enable him to purchase the insulin necessary at its present cost, and he may suffer hardship through inability to obtain it. The Board accordingly recommend parish councils to give sympathetic consideration to any application for assistance in the provision of insulin by or on behalf of any person falling within the class referred to above.

CATHOLIC MEDICAL GUILD FOR EDINBURGH.—The inaugural meeting of the Catholic Medical Guild of SS. Luke, Cosmas, and Damian was held at the Lauriston Hall, Edinburgh, on Feb. 21st. Dr. George Matheson Cullen is the Master of the Guild, with the Rev. Thomas J. Agius, M.D., for spiritual director and Dr. Isabel M. A. Doeg as hon. secretary. The guests included Canon Mullan, Canon McGettigan, Fr. J. Nicholson, Fr. Lennon. Mgr. T. Miley proffered an apology for his inability to attend. The address was given by Dr. Thomas J. Colvin, of the Glasgow Branch of the Guild. He dwelt on the widespread influence of the Catholic Medical Guild, not only in the British Isles but on the Continent and wherever the Catholic faith was spread. Its importance as a means of adjusting medico-ethical relations and of spreading sound scientific and moral principles might be gauged by the activities of the various branches. After a vote of thanks to the speaker, the meeting took up a discussion on birth-control, examining it in relation to the natural law, to the marriage contract, the duties towards society and the Supreme Lawgiver, as well as in its relation towards the fact of Christianity. On each of these four main grounds the meeting rejected and condemned the artificial interference with the physiological and psychological laws of reproduction as contrary to the Christian code of morality and against the natural law.

The official organ of the Catholic Medical Guild is the *Catholic Medical Guardian*, edited by Lieut.-Colonel P. W. O'Gorman, C.M.G., I.M.S., and published by Messrs. Burns, Oates, and Washbourne, 28, Orchard-street, London, S.W. 1.

Parliamentary Intelligence.

HOUSE OF COMMONS.

TUESDAY, MARCH 4TH.

Encephalitis Lethargica.

Mr. ALFRED T. DAVIES asked the Minister of Health whether there had recently been an increase of sleepy sickness (encephalitis lethargica) in various districts; to what was this increase attributed; and what were the conclusions of the medical experts who had been dealing with the situation.—Mr. WHEATLEY replied: The notification returns show that encephalitis lethargica has increased in prevalence during the past four weeks, but that this increase has occurred almost entirely in Lancashire. The disease is one which shows notable seasonal variations, both general and local, but the cause of these variations is at present obscure.

WEDNESDAY, MARCH 5TH.

Insurance Patients in Poor-law Hospitals.

Sir KINGSLEY WOOD asked the Minister of Health whether he had received any representations from boards of guardians calling attention to the number of persons insured under the National Insurance Acts who were admitted to Poor-law hospitals and in respect of whom the guardians were precluded from receiving any benefit for the treatment afforded; and whether he proposed to take any action in the matter.—Mr. WHEATLEY replied: Representations to the effect referred to by the hon. Member have been received, but I would point out that boards of guardians have the ordinary powers of recovery of expenses incurred by them in providing treatment in a Poor-law hospital to a person insured under the National Health Insurance Acts as in the case of all other persons for whom such treatment is provided.

Wrongful Detention in an Asylum Case.

Mr. PENNY asked the Attorney-General whether the whole or any part of the damages awarded against the defendants in a case of wrongful detention in an asylum tried in the King's Bench Division of the High Court of Justice recently was to be paid by the Crown.—Mr. WHEATLEY replied: An appeal is being entered against the judgment in this case. Under the judgment the sum of £5000 is to be paid to the plaintiff by the defendant, Dr. Bond. In accordance with the principle always observed where a public servant is sued in respect of actions taken in performance of his duty and the Crown undertakes the defence, this sum will be paid from public funds. An advance of £5000 is accordingly being made from the Civil Contingencies Fund, and the House will be asked to vote this sum and any further sum that may be found necessary by a supplementary vote on the Board of Control estimates. As the appeal case is sub judice it would not, I think, be possible to debate the case in the House pending the result.

Dissolution of Poplar and Stepney Asylum District.

Mr. LANSBURY asked the Minister of Health whether he was aware that the guardians of the Poplar parish were very strongly opposed to the dissolution of the Poplar and Stepney sick asylum district recently sanctioned by him; whether he would explain why he had agreed to the amalgamation of the Poor-law unions within the Stepney borough into one union, leaving Poplar as the one parish in the Tower Hamlets outside the scheme; and whether, in view of the fact that the Government was now pledged to deal with the reform of the Poor-law, he would reconsider his decision and postpone the dissolution of the district and the unification of the unions named above until the whole question of the reform of the Poor-law had been dealt with in a comprehensive manner.—Mr. WHEATLEY replied: I am aware of the facts stated in the first part of the question. The change which I have approved is in the direction of making Poor-law and municipal areas conterminous, and, as my hon. friend knows, it is not to take effect until March 31st, 1925. If a scheme of reform is brought into operation before that date this particular question will no doubt be merged in the larger issue, but in the meantime I see no need to alter my decision.

Trevethin Report and Venereal Disease.

Mr. WALTER GUINNESS asked the Minister of Health whether Clause 16 of the Trevethin Report dealing with the expenditure of money for reducing venereal disease has yet been considered by the Government; whether the question of Government financial assistance to the work of voluntary institutions has been decided; and whether, in view of the fact that the Society for the Prevention of Venereal Disease and the National Council for Combating Venereal Diseases had both unconditionally accepted the Trevethin Report, and had met in conference and had determined on joint

action for giving effect to its recommendations, he will cause the maximum grant, which is to be made by the Government, to be divided in an equitable proportion between the two organisations.—Mr. WHEATLEY replied: I have now under consideration the recommendations in the Trevethin Report, including the question of financial assistance from the Exchequer to the work of voluntary organisations, but I am not yet in a position to say how any Government grant for this purpose will be allocated.

Overcrowding and Small-pox.

Mr. FRANK LEE asked the Minister of Health whether he will direct medical officers of health to take note of the number of rooms in each house from which cases of small-pox are reported with the number of people living therein with a view to ascertaining whether, and, if so, to what extent, overcrowding has any bearing upon the prevalence of the disease.—Mr. WHEATLEY replied: Medical officers of health have already been asked to attempt to measure the influence of domestic overcrowding upon the incidence of notified diseases, and this is their usual practice. I will consider whether it is practicable to do anything further in regard to small-pox.

Immunising Children against Diphtheria.

Major MOULTON asked the Minister of Health whether his attention had been drawn to the remarkable results obtained by the Department of Health in New York in immunising children against diphtheria; and whether he proposed to take steps to enable parents who desire it to obtain the advantages of this treatment for their children free of charge.—Mr. WHEATLEY replied: The answer to the first part of the question is in the affirmative. This form of preventive treatment was the subject of a special medical report by my department in 1921, and in July, 1922, a memorandum was issued to local authorities drawing attention to the practical advantages of the method. The question of offering the treatment to parents is for the decision of local authorities or the managing bodies of institutions, but my department has offered expert advice and assistance in the application of the treatment by those who desire to adopt it.

THURSDAY, MARCH 6TH.

Amalgamation of Naval and Military Hospitals.

Commander BELLAIRS asked the Chancellor of the Exchequer whether any advance had been made in amalgamating naval and military hospitals in different parts of the world and selling the surplus sites; and what had been the decision in regard to the military parade ground and naval hospital at Hong Kong, which occupy valuable sites and the former of which the business community of Hong Kong had been anxious to buy for a long time.—Mr. SNOWDEN replied: The War Office has assumed responsibility for the treatment of all naval sick at Gibraltar, and the Admiralty has taken over the treatment of military sick at Chatham, with the result that one naval and one military hospital has been closed. As regards Hong Kong, negotiations are proceeding between the War Office and the Colonial Government for an exchange of properties, which include the existing parade ground and military hospital. If and when a settlement of this question is reached the question of the hospital accommodation required by the navy and the army will be reconsidered.

Sanatorium Schools for Tuberculous Children.

Mr. TURNER asked the President of the Board of Education whether he would reconsider the restrictions imposed in Circular 1270, issued by the Board on July 5th, 1922, under which the grant payable to the managers of voluntary sanatorium schools for tuberculous children was to be limited in respect of 1922–23 to the amount payable on the average attendance for the year 1921–22.—Mr. C. TREVELYAN replied: I do not propose to maintain the restrictions imposed by Circular 1270 on the amount of grant payable to managers of voluntary sanatorium schools which are in receipt of grant from the Board.

Deaths from Lead Poisoning.

Mr. EDMUND HARVEY asked the Secretary of State for the Home Department whether, seeing that the report of the Chief Inspector of Factories showed that a larger number of deaths from lead poisoning occurred in 1922 than in any previous year since 1900, what steps he proposed to take in order to put an end to the loss of life in the industries concerned.—Mr. HENDERSON replied: I presume the hon. Member refers only to the pottery industry. In no other industry was there a larger number of deaths from lead poisoning in 1922 than in any previous year since 1900. The hon. Member must not take the number of fatal cases from lead poisoning in 1922 as affording any indication of present conditions. In most fatal cases the disease has been contracted a long time previously, and as the hon. Member will find from the particulars of the 1922 cases, which will be circulated with the official report, the deceased had, in practically every instance, been employed for a long period of years in the industry. In fact, with few exceptions, the period of employment was not less than 20 years, and in two cases the worker had ceased to be employed in the industry some years previously. After an exhaustive inquiry by a departmental committee a new code of regulations for the industry was brought into operation in 1913, and since then there has been a great reduction in the total number of cases. Every effort is being made to reduce the number still further, but the hon. Member may rest assured that the situation will be carefully watched.

Mr. EDMUND HARVEY asked the Secretary of State for the Home Department whether his attention had been called to the fact that out of the 42 cases of lead poisoning notified in 1922 among workers in the manufacture of china and earthenware 17 were fatal; and whether he could give the ages and sex of those who died and state on what processes they were employed.—Mr. HENDERSON replied: The numbers stated in the question are those given in the report of the Chief Inspector of Factories for 1922. The following are the particulars asked for, together with the duration of the worker's employment in the industry:—

Case No.	Sex.	Age.	Duration of employment.	Process.
1	M.	51	35 years.	Glost placer.
2	M.	44	31 ,,	Dipper.
3	M.	53	Over 20 ,,	Glost placer.
4	M.	44	Not worked since 1916.	,, ,,
5	M.	43	28 years.	,, ,,
6	M.	58	29 ,,	,, ,,
7	M.	51	30 ,,	Dipper.
8	M.	60	41 ,,	Glost placer.
9	M.	60	46 ,,	,, ,,
10	M.	40	20 ,,	Dipper.
11	M.	55	37 ,,	Glost placer.
12	M.	61	Over 40 ,,	Dipper.
13	M.	44	31 ,,	Glost placer.
14	M.	42	16 ,,	,, ,,
15*	F.	55	7 ,,	Dipper.
16	F.	61	23 ,,	Aerographer.
17	F.	46	Not worked since 1904.	Warecleaner.

* Died of cancer of the stomach accelerated by lead poisoning.

Assaults on Children.

Sir THOMAS BRAMSDON asked the Secretary of State for the Home Department if he had received copies of resolutions, passed by various organisations and public bodies with reference to assaults upon children, calling attention to the inadequate sentences passed on offenders, and to the need for an investigation; and whether, in order to lessen the number of these offences, he would appoint a departmental committee with wide terms of reference, including medical and legal experts, social workers, and representative women, to inquire into the whole subject.—Mr. HENDERSON replied: My attention has been called to this matter, and I have arranged that a conference shall be held at the Home Office when the whole question can be discussed. As at present advised I do not think that any useful purpose would be served by the appointment of a departmental committee.

Pensions for Blind Ex-Soldiers.

Lieut.-Colonel RUDKIN asked the Minister of Pensions if he was aware that there were many ex-Service men who had become blind since their discharge, but were not in receipt of any State aid; and whether he would give an opportunity for such cases to be sympathetically considered by his department, with a view to pension or other assistance.—Mr. F. O. ROBERTS replied: I am not aware of any cases of blinded ex-Service men, whose condition is either due to or aggravated by war service, who are not in receipt of pension from my department.

Small-pox in England and Foreign Countries.

Mr. BROAD asked the Minister of Health the number of cases of, and deaths from, small-pox reported in Germany, Japan, and England and Wales, respectively, during each of the years 1921, 1922, and 1923.—Mr. WHEATLEY replied: The following statement gives such particulars as are available, although the figures are not necessarily strictly comparable:—

—	Number of—	1921	1922	1923
Germany	cases	688	215	17*
	deaths	?	?	?
Japan	cases	889	?	?
	deaths	212	?	?
England and Wales	cases	336	973	2500*
	deaths	5	27	7*

* Provisional figures.

MONDAY, MARCH 10TH.

Ship-breaking Workers.

Mr. WATSON asked the Minister of Health if his attention ad been drawn to the injurious effect of ship-breaking on ie health of the workers engaged in that industry; if he as aware that the men engaged on the acetylene burners ere only able to continue for a few weeks without breaking own; that in many cases no effective gas-masks or fresh ilk was provided; and would he take steps to inquire nto this matter and bring pressure to bear upon the ship-reaking companies to protect the health of their workers.—Ir. HENDERSON, the Home Secretary, replied: I have been sked by my right hon. friend to reply. The employment a question which has developed rapidly during the last wo or three years has given rise to a number of cases of ead poisoning. It has been receiving the special attention f the Factory Department, and as a result of visits by the edical inspectors arrangements have now been made by he occupiers of practically all the yards for a periodic edical examination of the workers, this being, I am dvised, the most practicable and effective precaution. It s hoped that these arrangements will prove effectual, but he situation will be carefully watched, and, if necessary, urther measures will be considered.

National Insurance Commission.

Sir KINGSLEY WOOD asked the Prime Minister if he ould announce the terms of the Royal Commission on Vational Insurance.—Mr. MACDONALD replied: The terms of eference have been drafted provisionally, but are not yet nally settled. A promise was given that before they were ettled they should be shown to representatives of the edical profession and of the approved societies.

Harnett v. *Bond and Adam.*

Mr. COMYNS CARR asked the Prime Minister whether he ad now come to a decision as to the promised inquiry into he questions of lunacy law and administration raised by the ase of Harnett *v.* Bond and Adam; and whether he could now ive an undertaking that the inquiry would not be held up ending the determination of possible appeals in that case o the Court of Appeal and the House of Lords.—Mr. OSTELLO asked the Prime Minister whether, when setting p the proposed body to inquire into the present lunacy aws and their administration, he would bear in mind the esirability of making the terms of reference to such body ufficiently wide to include an investigation into the internal dministration and management of public and private nstitutions for the detention of lunatics, with special egard to their treatment and the conditions under which hey received visitors and correspondence; and whether e would instruct such body to inquire into and report pon the feasibility of establishing hospitals to which oubtful cases might go for treatment, without unneces-arily incurring for themselves and their families the stigma f insanity.—Mr. MACDONALD replied: An application as been made to the Court of Appeal for an early hearing f this case, and the Court of Appeal have intimated their villingness to afford as early a hearing as possible. The pplication was made to prevent the possibility of embarrass-ment to any committee that may be appointed by reason f the Harnett case being still sub judice. In these circum-tances it is not possible for me, at this moment, to give ny undertaking such as is suggested, but the suggestions f Mr. Costello regarding the terms of reference will be orne in mind. Meanwhile the preliminaries to setting up he Commission are being proceeded with.

Sheffield Hospital Scheme.

Mr. CROOKE asked the Minister of Health if he was aware f the scheme by which the Sheffield hospitals were run by joint council, with the result that the institutions were ow self-supporting; and whether he would institute an nquiry into the working of this scheme in order to facilitate ts adoption in other municipalities, in view of the financial ifficulties at present obtaining in most hospitals.—Mr. REENWOOD replied: The Sheffield Joint Hospitals Council re not responsible for the administration of the voluntary ospitals in their area, but my right hon. friend is aware f the admirable work done by the council in organising he systematic collection of weekly contributions. It is ot necessary to institute any inquiry into the working of he Sheffield scheme, as this is already well known among ospital authorities. The adoption of this or other schemes f mass contribution in other areas is a matter for local ecision, but my right hon. friend is glad to learn that he question has been engaging the attention of many ocal voluntary hospital committees.

Future of Convalescent Centre.

Mr. HENDERSON asked the Minister of Pensions if he would state the number of trainees who had been discharged since Jan. 1st, 1924, from the Prince of Wales's Convalescent Centre, Barry, South Wales; whether he would suspend all further discharges; and whether he would give an assurance that this centre was not to be closed.—Mr. F. O. ROBERTS replied: The number is 120. As I have already stated the future of this centre is under consideration, but discharges must necessarily continue as the men complete their courses of treatment and training.

TUESDAY, MARCH 11TH.

Sulphuric Ether.

Mr. LORIMER asked the President of the Board of Trade if he would state the number of gallons of sulphuric ether imported into this country during 1923, and the number of gallons produced in Great Britain during the same period.—Mr. SIDNEY WEBB replied: The total quantity of sulphuric ether registered as imported into the United Kingdom during the year 1923 was 16 gallons. This quantity is inclusive of direct imports, if any, into the Irish Free State up to March 31st of the year in question. I am not in a position to state the quantity of sulphuric ether produced in the United Kingdom during the past year.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

D. Glass to be Surg.-Lt.

Surg. Comdr. G. E. Duncan is placed on the Ret. List, with the rank of Surg. Capt.

Surg.-Lt. (Emergency) R. R. Baker is reinstated on Active List as Surg.-Lt.

Surg.-Lt. J. R. Brennan to be Surg. Lt.-Comdr.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. H. Rogers retires on ret. pay.

Maj. and Bt. Lt.-Col. W. F. Ellis to be Lt.-Col.

Capt. T. R. Snelling retires, receiving a gratuity.

TERRITORIAL FORCE.

Maj. (Prov.) A. R. Moodie is confirmed in his rank.

Capt. C. Douglas to be Maj. (Prov.).

Capts. F. Harvey, D. L. Wall, and R. L. Williams, having attained the age limit, are retd., and retain the rank of Capt.

G. H. R. Gibson (late Canadian Army Med. Corps) to be Capt.

Lt. A. H. Richardson to be Capt. (Prov.).

ROYAL AIR FORCE.

R. H. Stanbridge is granted a short service commission as a Flying Officer.

Flight Lt. J. C. T. Fiddes is transferred to the Reserve, Class D.2.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.

THURSDAY, March 20th.—4.30 P.M., *Papers to be read:* Sir Charles Sherrington, P.R.S., and E. G. T. Liddell: Reflexes in Response to Stretch (Myotatic Reflexes). R. Campbell Thompson: The Plants of the Assyrian Medical Tablets. (Communicated by W. B. Hardy, Sec. R.S.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, March 18th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for election to the Fellowship (names already circulated.)

PATHOLOGY: at 8.30 P.M.
Annual General Meeting.
Election of Officers and Council for 1924–25.
Demonstrations:
W. D. Newcomb: Cutaneous Dissemination in Carcinoma of the Breast.
Nathaniel S. Lucas: (1) A Spleen and Liver from an Ocelot suggestive of a Leukæmic Condition; (2) An Unusual Form of Avian Nephritis; (3) An Angioma from the Liver of a Slender Dog.
Papers:
A. B. Rosher: The Effects of Inoculation of Heterologous Antigens on a Steady Agglutination Titre, with reference to the Diagnosis of Enteric in Inoculated Subjects.
V. F. Allison: Effect of the Administration of Vaccine on the Lysozyme Content of Tissues and Secretions.

Wednesday, March 19th.

HISTORY OF MEDICINE: at 5 P.M.
Papers:
Mr. J. E. H. Roberts: The History of Trusses.
Mr. George W. Corner: Earliest Western Anatomical Texts.

Thursday, March 20th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases will be shown

Friday, March 21st.

ELECTRO-THERAPEUTICS: at 8 P.M.
Discussion:
On the Clinical Results of Deep X Ray Therapy, to be opened by Dr. Harrison Orton, followed by Dr. William Mitchell (Bradford), Mr. Sampson Handley, Dr. Woodburn Morison (Manchester), Dr. Hope Fowler (Edinburgh), Dr. George Cooper (Leeds), Dr. Robert Knox, and Dr. Reginald Morton will take part.
N.B.—The X ray department of the Institute of Anatomy, University College, Gower-street, W.C. 1, will be open for inspection in the afternoon.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. 1.
MONDAY, March 17th.—9 P.M., Dr. R. A. Young: The Treatment of Pulmonary Tuberculosis. (Third Lettsomian Lecture.)

HARVEIAN SOCIETY OF LONDON.
THURSDAY, March 20th.—8.30 P.M., Meeting at Paddington Town Hall, Prof. J. E. Frazer: Annual Harveian Lecture.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.
THURSDAY, March 20th.—8.15 P.M., a Laboratory Meeting will be held at the Royal Army Medical College, Grosvenor-road, Millbank, S.W. The following, amongst others, will give Demonstrations: Lieut.-Colonels S. P. James, W. P. Macarthur, and H. Marrian Perry; Drs. J. G. Thomson, Broughton-Alcock, and C. M. Wenyon; I. M. Puri, M.Sc., and L. G. Saunders, M.Sc., of the Molteno Institute, Cambridge (by permission of Prof. G. H. F. Nuttall). Dr. Andrew Balfour, C.B, C.M.G., will show a Cinematograph Film—lent by the Rockefeller International Health Board—illustrating the Ætiology, Spread, and Prevention of Malaria.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W. 1.
TUESDAY, March 18th.—8.30 P.M., Dr. Percy B. Spurgin and Sir Bernard Spilsbury: Cases of Sudden Death from Inhibition and their Medico-Legal Bearings.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
TUESDAY, March 18th.—5 P.M., Lieut.-Colonel Glen Liston, C.I.E.: The Plague. (Last Milroy Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.
MONDAY, March 17th, to SATURDAY, March 22nd.—BETHLEM ROYAL HOSPITAL. Course in Psychological Medicine. Tues. and Sat., 11 A.M., Dr. Thomas Beaton and Dr. Porter Phillips: The Psychoses.—CHELSEA HOSPITAL FOR WOMEN. Daily: Operations, &c. Mon., 2 P.M., Mr. Rivett: Affections of the Vulva. Tues., 5 P.M., Mr. Bonney: Symptoms produced by Pelvic Displacement. Wed., 2 P.M., Mr. Dodd: Salpingitis. Thurs., 2 P.M., Mr. Giles: Plastic Operations demonstrated in Modelling Clay. Fri., Mr. Comyns Berkeley: Operations.—ROYAL FREE HOSPITAL. Wed., 5.30 P.M., Dr. Heald: The Direct Current especially in Relation to Fractures and Injuries.—ROYAL WATERLOO HOSPITAL. Lecture-Demonstrations, Ward Work, &c. Mon., 2 P.M., Dr. Woodwark; 3 P.M., Dr. Barron; 4 P.M., Dr. Donaldson. Tues., 2 P.M., Dr. Moon; 3 P.M., Dr. Myers; 4 P.M., Dr. Davidson. Wed., 1.30 P.M., Mr. Cairns Forsyth. Thurs., 1.30 P.M., Dr. Perkins; 2.30 P.M., Mr. Bickerton; 3.30 P.M., Dr. Tindal-Atkinson. Fri., 1 P.M., Dr. Lyle Cameron; 2 P.M., Dr. R. J. Perkins; 4 P.M., Mr. Beevor. Sat., 9.30 A.M., Mr. Frankau (Operations). Further particulars can be obtained from the office, 1, Wimpole-street, W. 1.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, March 17th.—10 A.M., Surgical Registrar: Surgical Pathology. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Addison: Surgical Wards.
TUESDAY.—12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept. 2 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 12.15 P.M., Dr. Burnford: Medical Pathology. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
FRIDAY.—10.30 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Dr. Burrell: Medical Out-patients. Mr. Sinclair: Surgical Out-patients.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.
WEDNESDAY, March 19th.—5 P.M., Prof. E. Gorter, of Leiden: The Pathogenesis of Certain Nutritional Disorders. (University of London Lecture in English.)
THURSDAY.—4 P.M., Dr. Cockayne: Mental Deficiency.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital.
(At 4.30 P.M.)
MONDAY, March 17th.—Dr. S. Cochrane Shanks: The X Ray Examination of Joint Conditions.
TUESDAY.—Dr. F. G. Crookshank: Treatment of Acute Pneumonia.
WEDNESDAY.—Dr. J. Browning Alexander: Pulmonary Fibrosis.
THURSDAY.—Mr. W. E. Tanner: Fractures of the Forearm and Elbow.
FRIDAY.—Dr. Jenkins Oliver: Some Skin Diseases of Infancy and Early Childhood.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE: FEBRUARY–MARCH, 1924.
CLINICAL LECTURES AND DEMONSTRATIONS.
MONDAY, March 17th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Disseminated Sclerosis: Dr. Birley.
TUESDAY, March 18th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Cervical Rib: Mr. Armour.
THURSDAY, March 20th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., The Neuroses: Dr. Hinds Howell.
FRIDAY, March 21st.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Demonstration of Ward Cases: Dr. Grainger Stewart.
COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.
MONDAY, March 17th.—12 noon, Motor Neuron Disease: Dr. J. G. Greenfield.
The fee for the Course, including Pathology, is £5 5*s*. For those who hold Perpetual Tickets the fee is £3 3*s*.
COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.
WEDNESDAY, March 19th.—3.30 P.M., The Trigeminal Nerve: Mr. Leslie Paton.
The Fee for this Course alone is £5 5*s*. If taken in conjunction with the general Post-Graduate Course the Fee is £3 3*s*. All applications should be sent to the Secretary, Medical School.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.
Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course.
Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.
J. G. GREENFIELD, Dean of Medical School.

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, March 19th.—4.30 P.M., Sir James Dundas-Grant: Cases illustrating the Diagnosis and Treatment of Cancer of the Throat.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
TUESDAY, March 18th.—5 P.M., Dr. Barber: Bacteriology of the Skin.
THURSDAY.—5 P.M., Dr. Sibley: Malignant Disease. (Chesterfield Lecture.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, March 18th.—4.15 P.M., Dr. A. E. Barclay: The Large Intestine from the Radiological Point of View.

ANCOATS HOSPITAL LECTURES.
THURSDAY, March 20th.—4.30 P.M., Dr. W. J. S. Reid: Rheumatism of Venereal Origin.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, March 17th.—(At the Hospital for Women.) Dr. Willett: The Pelvic Peritoneal Crisis.
TUESDAY.—(At the Maternity Hospital.) Dr. J. W Burns: The Bleedings of Pregnancy.
WEDNESDAY.—(At the St. Paul's Eye Hospital.) At 3 P.M. Mr. Hayward Bywater: Glaucoma.
THURSDAY.—(At the St. George's Skin Hospital.) Dr. Barendt: Skin Cases.

Appointments.

DOWNING, ETHEL, M.R.C.S., L.R.C.P. Lond., has been appointed House Surgeon to the New Sussex Hospital for Women and Children, Brighton.
MACDONALD, J. B., M.B., Ch.B. St. And., Resident Medical Officer, East Poor House and Hospital and Ashcliffe Children's Home.
SMITH, H., M.R.C.S., L.R.C.P. Lond., Police Surgeon under the Leeds Corporation.
WILLIAMS, ENID A., L.R.C.P. & S. Edin., L.R.F.P.S. Glasg., D.P.H., Resident Medical Officer, Wolverhampton Poor-law Institution.
WOLFERSTAN, K., M.R.C.S., L.R.C.P. Lond., Certifying Surgeon under the Factory and Workshop Acts for Crewkerne.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, Greenwich, E.—H.S. £150.
Barbados General Hospital.—Jun. Res. S. £250.
Bradford City.—Bacteriologist and Pathologist. £750.
Bradford Royal Infirmary.—Three H.S.'s. H.P. Each £150.
Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.
Burntwood, near Lichfield, County Mental Hospital.—Med. Supt. £1000.
Burton, Derbyshire, Devonshire Hospital.—Asst. H.P. £150.
Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—H.S. £100. Jun. H.S. £50.
Charing Cross Hospital, W.C.—Asst. Obstet. P.
Chester Royal Infirmary.—Asst. H.S. £150.
Coventry and Warwickshire Hospital.—Res. H.S. £150.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Morning Cas. O. £120.
Evelina Hospital for Children, Southwark, S.E.—H.S. and H.P. Each £160.
Federated Malay States, Central Mental Hospital.—Asst. Med. Supt. £616.
Greenwich, Dreadnought Hospital.—H.S. and H.P. Each £150.
Hastings, Royal East Sussex Hospital.—Secretary. £500.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S., H.P., and Asst. Cas. O. £50.
Infants Hospital, Vincent-square, Westminster.—Jun. Anæsthetist.
Kensington Board of Guardians, Marloes-road Hospital.—Temp. Asst. M.O. £7 7*s.* weekly.
Leicestershire and Rutland Mental Hospital, Narborough, near Leicester.—Second Asst. M.O. £350.
Liverpool Eye and Ear Infirmary.—Hon. Pathologist and Hon. Asst. Aural S.
London Lock Hospital, 91, Dean-street, W.—H.S. £200.
Manchester Royal Infirmary.—Hon. Asst. Aural S.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. S.
Prince of Wales's General Hospital, Tottenham, N.—Two H.S.'s. H.P. Each £150. Jun. H.S. and Jun. H.P. Each £110.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Pathologist. £300. Also Asst. S.
Redhill, Surrey, Royal Earlswood Institution.—Jun. Asst. M.O. £250.
Rochdale Infirmary and Dispensary.—Jun. H.S. £200.
Rotherham Hospital.—Jun. H.S. £150.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. P.
Sheffield Royal Hospital.—Res. Surg. O. £200.
Warrington, Lancashire County Mental Hospital, Winwick.—Asst. M.O. £440.
West London Hospital, Hammersmith-road, W.—One H.P. and Two H.S.'s. Each £100.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. Non-Res. H.S.'s. £150 and £100 respectively.

The Chief Inspector of Factories, Home Office, London, S.W., announces a vacant appointment at King's Lynn, Norfolk.

Births, Marriages, and Deaths.

BIRTHS.

PARIS.—On Feb. 6th, at Quetta, India, the wife of Major R. C. Paris, R.A.M.C., of a daughter.
SUNDERLAND.—On March 3rd, at 1D, Hyde Park-mansions, London, N.W., the wife of Arthur Sunderland, M.R.C.S., L.R.C.P., of a daughter.

MARRIAGES.

BARLOW—ROWNEY.—On March 4th, at St. Bartholomew-the-Great, Smithfield, Dr. Albert Malcolm Barlow to Dr. Eileen Susan Pears Rowney.

DEATHS.

BROAD.—On March 8th, at The Sanatorium, Cardiff, Major B. W. Broad, M.B., C.M., Medical Superintendent.
DAVIES.—On March 8th, at Bryn-Newydd, Sketty, Glamorgan, David Arthur Davies, M.B. Lond., J.P., aged 75.
HAMMOND-SMITH.—On March 4th, at St. Albans-mansions, Kensington-court, W., Henry Hammond-Smith, L.R.C.P., M.R.C.S., aged 73 years.
LAWRENCE.—On March 8th, at Chepstow, Arthur Garnons Lawrence, M.D., in his 88th year.
NEW.—On the 9th March at a nursing home, of pneumonia, John Sherwood New, M.B., B.S., D.P.H., aged 53, Medical Officer of Health for Amersham, Bucks; Physician in charge Stoke Newington and St. Pancras Infants' Welfare Centres. Funeral from 245, Knightsbridge, S.W. 7. No flowers.
NEWBOLT.—On March 9th, suddenly, at his residence, 5, Gambier-terrace, Liverpool, in his 61st year, George Palmerston Newbolt, C.B.E., F.R.C.S., dearly loved husband of Lila Newbolt.
PARK.—On March 8th, at Rosedale, Torquay-road, Paignton, David Scott Park, J.P., F.R.C.S. Edin., &c., in his 80th year.

*N.B.—A fee of 7*s.* 6*d.* is charged for the insertion of Notices of Births, Marriages, and Deaths.*

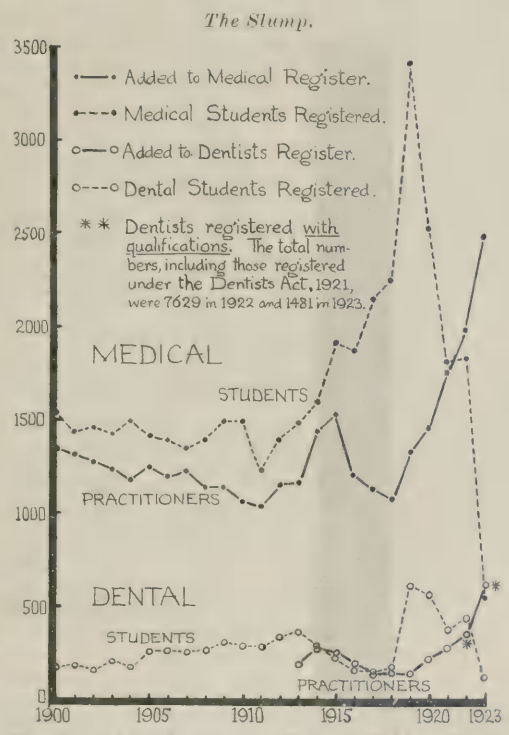
Notes, Comments, and Abstracts.

THE PORTAL OF MEDICINE.

ENTRIES OF STUDENTS AND PRACTITIONERS IN 1923.

In his presidential address to the General Medical Council in August, 1921, Sir Donald MacAlister pointed to the high tide of registration for medical study and expressed a misgiving whether the position had not been reached in which danger might arise to professional education, and perhaps to professional careers, from the mere number of students entering. That danger exists no longer, for the phenomenal rise in the entry of 1918–20 has been followed by a decline in numbers, alike without precedent. From the Medical and Dental Students Register, to which allusion was briefly made last week, it appears that the entry of medical students for 1923 was less than one-third of the entry for 1922. The same is true of the dental students except that a precedent for the small number can be found in 1887 and preceding years. The Medical and Dental Registers, on the other hand, show high-water marks in 1923 for professional registration, and these figures are likely to be maintained for another year or two. The accompanying graph based upon these figures sets out the situation and

The Slump.



The stippled band represents the period of hostilities, 1914–1918.

gives occasion for thought. While the drop in medical and dental entries may be nothing more than the trough succeeding the wave of the immediate post-war years, it must be due in some measure to the lessened entry of women students in particular. The latest report of the University Grants Committee—namely, for the year 1922–23—already shows a diminution of medical students to the number of 32 men and 246 women. Moreover, judging by the Christian names in the G.M.C. list of students, there are hardly more than 60 women among the total 545 medical entrants of 1923. The Grants Committee's report calls attention to the reasons which served to draw young men and women after the war to the medical schools and departments, but it does not foreshadow any such tremendous reduction in the entry as is shown by the 1923 figures. The diminution may have its root in economic conditions; possibly in a belief among parents that the medical profession is likely to be overcrowded or does not present a fair prospect of livelihood. No doubt the relatively high cost of the medical curriculum is a contributing factor.

CENTENARY OF THE GLASGOW EYE INFIRMARY.

THE Glasgow Eye Infirmary began its work, albeit humbly, in June, 1824, and it will thus attain its majority, as one may say, in June, 1924. The founding of an eye hospital in Glasgow was first conceived by Dr. William Mackenzie, who circulated locally in January, 1824, a small pamphlet calling attention to the need for such an institution in the City, and he received enthusiastic support from another Glasgow surgeon, who had already established a considerable reputation in ophthalmology—Dr. George C. Monteath. After various preliminaries it was decided, at a public meeting with the Lord Provost in the chair, that an eye infirmary based on Dr. Mackenzie's suggestions should be established. The result was that a small house in a rather obscure lane almost in the centre of the city was opened in June, 100 years ago, for the care and treatment of sufferers from eye diseases.

The first surgeons were, as was to be expected, Mackenzie and Monteath, and it was arranged that each should take duty for a period of three months at a time and should attend at the infirmary three days a week. At first there was no special provision for operative treatment; the surgeons attended patients at their own homes and performed such operations as were needful there. In 1825 two beds for indoor patients were provided and a man and his wife were employed as nursing attendants. Subsequently two additional beds were supplied. In 1834 the premises at 19, Inkle Factory-lane (off North Albion-street) became too small and a house at 14, College-street (off High-street) was purchased. In this house ten patients could be accommodated, and the nursing staff remained as it was. In 1851 the work had increased to such an extent that premises of a better type became essential and the house in Charlotte-street was purchased. By 1874 continued growth had necessitated a further removal to the present buildings in Berkeley-street, and in 1886 an addition to the premises was completed.

There is now indoor accommodation for nearly 110 patients at Berkeley-street, as well as an out-patient department at which about 22,000 new patients attend each year. There is also an out-patient department in a new building erected in 1897 at Charlotte-street, where about 4000 new patients attend yearly. A branch of the eye infirmary has been opened at Clydebank for outdoor treatment of patients who reside in the neighbourhood of the shipyards and other works in that district. Thus the work began by Mackenzie has grown from small beginnings to very considerable proportions. The statistics of the Glasgow Eye Infirmary show that the amount of work done is great and it may be said that the state of the funds of the institution indicates that, after a hundred years of service, the public of the city recognises its merits.

Two or three little points in medical history may be noted. Tenotomy for squint was first performed in 1840 and depression for cataract was last performed in 1849. The epidemic of relapsing fever which raged in Glasgow about 1853 has left its mark in the statistics of the infirmary. Lastly, it is striking how great a decline there is in the proportion of cases of ophthalmia neonatorum to the total number of new cases. In 1840 it was nearly 1 in 10 and it gradually declined to 1 in 500.

In view of the celebration of the centenary a committee has been appointed to consider what form of memorial would most fittingly mark the occasion.

A MEDICAL ACCOUNT BOOK.

WE have received a copy of Henry's Account Book,[1] which is designed for the use of members of the medical profession. If one is prepared to give the necessary time or attention to filling it up it will simplify many common difficulties and satisfy queries raised by the inspector of taxes. Whilst the headings used are suitable for ordinary purposes others might be required, and a little space more for extra blank columns would have been an improvement. This account book will be of value to medical men.

PUBLIC HEALTH IN BRITISH HONDURAS.

THE estimated population of this colony on Dec. 31st, 1922, was 45,717 (males 22,688, females 23,029). The birth-rate for the year 1922 worked out at 39·059 per 1000, as compared with 35·456 in 1921, and the death-rate was 30·752 per 1000, as against 24·507 in the previous year. There was an alarming rise in the number of infant deaths. This was partly accounted for by an epidemic of whooping-cough. In the Orange Walk and Corozal districts the disease was very prevalent, and was of a virulent type, no less than 80 deaths in Corozal and 25 in Orange Walk having been certified as occurring from it. There were registered during the year in Belize (the capital) 9 deaths from malaria, the average mortality for the previous four years having been 12. The morbidity from this disease, which is naturally more difficult to estimate accurately, is, according to most of the medical practitioners in the town, on the decrease—a fact due probably to the increased precautions in carrying out the Mosquito Destruction Ordinance and the more efficient cleaning of yards. Two deaths were registered from tetanus neonatorum, as against an average mortality of 4 during the previous four years. It is hoped that, the new type of trained midwife now gradually taking the place of the older generation in Belize, this disease may before long be completely eradicated. Deaths from malaria showed a proportion of 6·7 per cent., from tuberculosis of 9·2 per cent., and from broncho-pneumonia of 10·6 per cent. of all the deaths registered. The climate of British Honduras has the reputation of being very unhealthy, but facts show that it compares not unfavourably with that of other tropical countries with small European populations, and that Europeans leading a normal life and taking common precautions find it pleasant and healthy. The highest rainfall registered in 1922 was at Punta Gorda in the Toledo district, which had a total of 151·19 inches and 192 days on which rain fell. The lowest rainfall was at Corozal, which had a total of 27·10 inches. The hottest day was May 14th, on which the thermometer registered 93·5° F., and the coldest day Jan. 14th, when it registered 56° F.

[1] Compiled by Mr. D. H. Rosen, 122, St. George's-road, Bolton; and printed by Messrs. Abel Heywood and Son, Manchester.

FOR THE ASKING.

To the Editor of THE LANCET.

SIR,—May I ask through the medium of your columns whether a gift of three pairs of silk elastic stockings in quite good condition, though not new, would be useful either to an institution or to anyone interested in a deserving case? They were made to fit a female of middle height, and I should like to feel that they had gone where they were useful.

I am, Sir, yours faithfully,

March 11th, 1924. STOCKINGS.

THE PROTECTION OF AIRCRAFT FROM INSECTS.

AN admirable little book,[1] illustrated with figures borrowed from well-known text-books, and designed for the use of officers and other Government servants in East Africa, has reached us. The subject-matter deals with tropical disease and insect transmitters and is clearly and well expressed: the instructions are direct and dogmatic. The second portion, written for the guidance of airmen in this country, describes the various kind of wood-boring insects liable to damage the wooden portions of an aeroplane and the means that should be taken to protect machines from this damage in East Africa. A useful map showing the range of tsetse-flies in the country is inserted at the end of the book.

M. L. J.—The remuneration of the locum-tenent is much the same now as it has been for some years past. In an average practice, whether in town or country, the lowest fee for a trustworthy tenent is 8 guineas a week, plus board, lodging, and travelling expenses. In the case of unusually large practices or in colliery or manufacturing districts 10 guineas may be paid. Advertisements offering services at less than the standard rate should be scrutinised with care.

Lettsomian Lectures

ON THE

TREATMENT OF PULMONARY TUBERCULOSIS.

Delivered before the Medical Society of London

BY R. A. YOUNG, C.B.E., M.D., B.Sc., F.R.C.P. LOND.,

PHYSICIAN TO THE MIDDLESEX AND BROMPTON HOSPITALS.

LECTURE III. (*Delivered on March 17th.*)

METHODS OF SECURING LOCAL REST FOR THE LUNG.

THE established value of rest as a cardinal factor in the treatment of pulmonary tuberculosis rendered it fitting that attempts should be made to secure more complete rest to the affected lung than that afforded by simple recumbency. The success of strict local rest in the treatment of tuberculosis of the bones, joints, and spine offered also a direct incentive to attempts to achieve similar conditions for the pulmonary lesions. In this lecture I propose to consider the methods which have been devised to this end, with special reference to the indications for their application, their present limitations, and contra-indications. In this connexion it is well to remember that opinion is still in the making, and that with greater experience and with improved methods these forms of treatment may well prove to be of wider application by affording help to cases for which at present they seem unsuitable. This much may even now be affirmed, that they represent a real advance in treatment, that they have given help to cases in which other methods have failed lamentably, and that they have been the means of prolonging many lives and of restoring to active and useful life not a few patients whose outlook was at best one of chronic invalidism. It is much to be regretted that in this country, in which the original suggestions of several of these methods of treatment originated, they have been somewhat neglected until recently. There is now, however, gratifying evidence that their value is being widely recognised here, and they are now taking a recognised place in the scheme of treatment of this disease largely owing to the work of Lillingston, Pearson, Morriston Davies, Riviere, and Burrell. The recent report on artificial pneumothorax of Burrell and MacNalty, published by the Medical Research Council, is a very valuable analysis of the present state of this form of treatment, and a recent number of *Tubercle*[1] contains a valuable summary of the present position of thoracic surgery. To both of these publications I must here acknowledge my great indebtedness.

At the outset it may be well to stress the importance, indeed the absolute necessity, of X ray control of all methods directed to securing local rest to diseased lung tissue. Some years ago I asked Dr. Rist of Paris why it was that he found so many more cases suitable for artificial pneumothorax treatment than most British physicians. He replied that it was because he used X rays more than we did. As far as possible every case of active tuberculous disease of the lung should be examined with the X rays, and particularly all those not responding satisfactorily to ordinary methods of treatment. This examination may reveal the suitability of the case for these special methods of treatment, or demonstrate almost conclusively their impracticability. While these treatments are in progress X ray control is also of the greatest assistance.

1. SIMPLE MECHANICAL METHODS.

In cases where strict rest in bed fails to render the patient afebrile, attempts may be made to limit the respiratory movements of the affected lung, or even of the diseased part of the lung, by mechanical means such as by belts and strapping. This method was originally employed by Dr. F. T. Roberts in the treatment of painful pleurisy. He applied strapping to the affected side in a manner similar to its application in the immobilisation of fractured ribs. Various ingenious mechanical contrivances have been employed to restrict the movements of the affected side or of that part of the affected lung which is known to be most diseased. Application of sand-bags in such a way as to obstruct the movement of one side of the chest is sometimes employed. At Frimley we sometimes use an "apex belt" to lessen the excursion of the upper part of the chest. Dr. Wingfield has recently employed strapping in broad strips, applied with considerable force so as very effectively to limit the movement of one side of the chest. The strapping has necessarily to be reapplied when it slips to such an extent as to allow more movement again. Dr. S. H. Stewart[2] has devised an ingenious lung splint which he has used for the same purpose.

Recently Dr. S. A. Knopf[3] has claimed that what he describes as "rest breathing" is a useful adjunct to treatment. He maintains that animals which breathe slowly live longer and are less susceptible to tuberculosis than those breathing more quickly. He believes that "in controlled diaphragmatic breathing, aided, if necessary, by slight mechanical restrictions, we have the best substitute for artificial pneumothorax, particularly where the tuberculous lesion is limited to the upper portion of the lungs." He instructs the patient to breathe slowly and to use the diaphragm chiefly. He has found that the number of expirations can be reduced from 20 per minute to ten or less, with great advantage to the patient.

None of these methods should be persisted in if they increase pain or lead to cough and dyspnœa. They are often impracticable if there is emphysema. Knopf allows that his method is not to be used if there is great involvement of the lower lobes.

2. ARTIFICIAL PNEUMOTHORAX.

Mechanical methods such as those just described can at best only restrict the movement of the affected lung and limit the respiratory ventilation of that side. In some cases this restriction may be sufficient to quieten if not lessen the circulation through the diseased areas and to prevent absorption of toxic products. When these areas of disease are extensive and active these methods often fail and the case becomes an unfavourable one, involving very prolonged rest before quiescence is achieved or active spread with progressive deterioration and eventually death. To such cases artificial pneumothorax when practicable offers a further chance of improvement and arrest. The suggestion for its use in pulmonary disease is over a hundred years old, and is due to Dr. James Carson, of Liverpool. It was again suggested by Forlanini in 1882, and carried out by him in 1888, so that he must be regarded as the pioneer of this form of treatment, though it had been employed in France by Potain in 1884 to replace fluid in a hydro-pneumothorax. Cayley in 1885 had a pneumothorax induced by incision to endeavour to stop severe hæmoptysis. Murphy of Chicago used this form of treatment in 1898. Brauer improved the technique and added the water manometer to the apparatus for induction of the pneumothorax, thereby greatly lessening its risks.

Artificial pneumothorax was first used in this country by Lillingston in 1910, and next year cases were recorded by him and by Colebrook, Pearson, and Rhodes. It is now recognised as a valuable routine treatment for suitably selected cases by most workers in this country, and it is important that the indications and contra-indications for its employment should be more widely known.

[3] British Journal of Tuberc., 1923, xvii., No. 3.

Rationale of the Treatment.

Artificial pneumothorax treatment aims at allowing the lung to collapse by admitting sterile air, oxygen, nitrogen, or other gas into the pleura. The lung collapses in the first instance by its own elasticity, this being no longer controlled by the negative pressure in the pleural space. It is obvious that when this elastic recoil of the lung is complete the pressure in the pleura should be that of the atmosphere and that any further introduction of gas into the pleura will raise the pressure to a positive level, with the result that the lung will be subjected to a compressing force. It must also be borne in mind that these readjustments of the intra-pleural pressure involve alterations in the mediastinum, which is at first drawn to the opposite side till the pressure becomes zero, and afterwards pushed over to it, when the pressure becomes positive. The importance of manometer readings of these pressures is therefore apparent. They are further essential as affording the best means of determining when the needle is in the pleural space and when the air or gas may safely be allowed to pass into this space. In the induction of a pneumothorax the object is to get the lung to collapse by its own elasticity, and it is unnecessary and undesirable to introduce a large amount of gas at the first sitting or to obtain zero or atmospheric pressure, still less a definite positive. It is only later, when the question of incomplete collapse from adhesions or insufficient gas entry becomes apparent, that the question of increased pressure becomes important. It must be remembered that as in spontaneous pneumothorax, the altered pressure relations may lead to dyspnœa, pain, restlessness and cardiac embarrassment, and the onset of any of these symptoms during the treatment demands careful investigation. An excessive pressure may lead to the condition of mediastinal bulge or hernia, whereby the distended pleura transgresses the mediastinal area and appears as a definite projection towards the sound side. This is to be avoided if possible. In cases of incomplete collapse in which attempts are made to stretch or break down adhesions by gradual increase of pressure, failure often occurs, and the increased gas put in may lead to mediastinal bulge instead of to further lung compression. The present tendency is against high pressures and against attempts to break down adhesions by this means as not being devoid of risk. These points illustrate and emphasise the importance of X ray control of the treatment.

This form of treatment may also serve the very useful purpose of allowing lung tissue which is the site of an excavation to contract, thus reducing the cavity and promoting healing and fibrosis. In like manner it may be of value in severe hæmoptysis by contracting the lung tissue around the aneurysm or vessel from which the hæmorrhage comes.

It might be expected if there were active lesions in the opposite lung that they would become more active owing to the increased work thrown upon this lung. This, in point of fact, does occur, if there are extensive lesions present, and may necessitate abandonment of the treatment after it has been started. Where the lesions are localised and of comparatively slight activity, however, there may be a definite beneficial effect and these lesions may progress satisfactorily to arrest. This may be due to increased vascularity of this side, which has been supposed to occur, or to a cessation of focal reactions owing to the prevention by the collapse produced, of auto-inoculations from the more diseased side.

Indications and Contra-indications.

In spite of its great and well-established value artificial pneumothorax is not a form of treatment to be lightly applied. Every case must be considered from many aspects to determine whether the treatment is likely to benefit the patient and to improve his chances of recovery. The actual indications are still subject to discussion, though there is general agreement as to most of them. It is most suitable for patients in whom the disease is confined to one lung or in whom, if bilateral, there are only localised or slightly active lesions on the side less involved. It is difficult to lay down a standard as to what extent of disease in the second lung renders the operation likely to fail. Each case must be considered as an individual problem, after careful review of the symptoms, the signs, the X ray findings, the physique, and the general condition of the patient, with special reference to the condition of the circulatory system.

These conditions being fulfilled we may consider artificial pneumothorax (1) in cases in which, in spite of treatment in a sanatorium or on sanatorium lines the disease is obviously active and spreading and there is fever, with cough and expectoration or signs of caseation. The question as to how long ordinary treatment is to be persisted in is a difficult one, and no hard-and-fast rule can be made. Dr. Burrell suggests that the treatment should be considered in any such patient who shows signs of activity after six months' medical treatment. On the other hand, it may jeopardise the chances of complete success if the decision is unduly postponed, and where the clinical signs and the radiographic examination indicate failure to secure arrest, the treatment should be started much earlier. (2) In cases with repeated severe hæmorrhages this form of treatment is of great value, and it offers a means of dealing effectively with the cause of the hæmoptysis. It may also be considered in cases of severe and prolonged hæmorrhage, which do not yield to the ordinary methods of treatment. (3) In patients who settle down and become afebrile under sanatorium treatment, but are left with cavities and with more or less copious expectoration containing tubercle bacilli. (4) In patients who are afebrile while in bed or while on restricted exercise, but who get auto-inoculations or become slightly febrile on attempting to work. (5) Cases with marked basic signs or with bronchiectasis, though pleural adhesion often renders it impracticable.

The contra-indications are more explicit, although it is possible that with increasing experience and modified methods some cases which are at present regarded as absolutely unsuitable may prove to be capable of benefit. The main contra-indications fall into two groups: (1) those due to the disease; (2) those due to the physique, temperament, and general medical state of the patient. To the first group belong (*a*) cases with active disease in the opposite lung, and this is absolute if it involves more than one-third of its extent; (*b*) if there are severe complications, such as tuberculous enteritis or bilateral renal tuberculosis. Laryngeal tuberculosis does not negative its employment unless it is very advanced. In the second group we may include (*a*) cases with poor physique, ill-nourished, and gravely debilitated; (*b*) those with feeble circulation, rapid pulse, and very low blood pressure; (*c*) severe visceroptosis is regarded by Dr. Burrell as a contra-indication; (*d*) cases complicated by other diseased conditions, notably diabetes, chronic nephritis, asthma, and advanced emphysema; (*e*) in patients over 60 (Lillingston); (*f*) both Burrell and Lillingston would exclude patients of highly neurotic tendency or with mental instability.

There remains a number of cases which are doubtfully suitable, in which the decision would depend upon the predilection and experience of the practitioner in charge. Among these we may include—

(*a*) *Early Cases.*—A few authorities regard early cases as suitable. The arguments against this have been well expressed by Dr. Clive Riviere in his book on this form of treatment. It is unnecessary in early cases which respond to sanatorium, climatic, or other medical methods within reasonable time, and since it involves some risks, which though small are not negligible, the balance seems to be against its employment in such cases. Moreover, the time it needs to be kept up and the necessary inconvenience it imposes

n the patient would hardly warrant its use as a primary method of treatment.

(*b*) In *acute cases*, especially if of broncho-pneumonic ype, its employment is more than doubtful. The isease is generally widespread and bilateral and ts progress rapid. Artificial pneumothorax is either napplicable because of the extent or if tried it usually ails. In the localised lobar pneumonic type of case may be tried cautiously if the opposite lung is not nvolved, if the general condition is good, and the ulse is not rapid.

(*c*) *Bilateral Cases.*—The question of bilateral neumothorax must be considered separately. It as been shown to be practicable, but it is still on its rial.

Technique of Artificial Pneumothorax.

The apparatus consists essentially of (1) a special eedle for puncture of the pleura. The form introuced by Dr. Clive Riviere is that usually employed or the primary induction, as being safer, owing to s blunt rounded end, while the sharper pointed needle f Saugman is used for refills. It is best to have a nall piece of glass tubing connected to the needle s in an ordinary paracentesis needle, so that blood r fluid may be seen if the needle enters a vein or a leural effusion. (2) A reservoir containing sterile r, oxygen, or other gas, generally a bottle connected ith a second bottle containing water, with arrangeents for adjusting their levels so that air or gas n be displaced from the reservoir by slight pressure. 3) A manometer containing coloured water, spirit, bromoform. (4) A three- or four-way glass tube ith rubber tube connexions to the reservoir, the anometer and the needle, each of which is controlled y a spring clamp. The fourth branch present in me forms is simply to allow of filling and cleaning. everal convenient forms are on the market, notably iat of Dr. Lillingston and Dr. Pearson, which is mple and portable. Dr. Parry Morgan recommends ie use of two manometers, and has designed a ecial form of apparatus with this feature. A simple rm is that used by Dr. Marshall, in which the gas contained in a rubber bag. It has the disadvantage at the quantity of gas introduced cannot be easured, nor can the pressure at which it enters observed.

The apparatus should be thoroughly tested before e to see that all connexions are correct and that l joints are air-tight. The tubes having been sterilised eviously, strychnine, ether, pituitrin, and a sterile ringe should be ready in case of shock or any other nergency.

The preparation of the patient and the actual chnique of the procedure are well described by . Burrell in the report to which I have already ferred, and in most of the cases in which I have ployed the treatment it has been carried out her by Dr. Burrell at Brompton Hospital or by . R. C. Wingfield at Frimley. Usually the tients to whom the treatment is applied are already afined to bed, but in any case they should be put bed till the pneumothorax is well established or til the temperature has subsided to normal. An erient the night before is desirable, and an injection morphine gr. ¼ or an equivalent dose of omnopon lf an hour before the operation. The patient should on the sound side, comfortably supported, with the e of the proposed puncture conveniently placed the operation. The favourite site for induction in the mid-axillary line in any space from the th to the ninth, though if failure results here trial y be made in the posterior axillary line, at the se behind, or in the second space below the clavicle, ough it is wise not to make more than two attempts one day, and Dr. Burrell states that four failures different situations render it unlikely that the atment is practicable. The skin having been nted with iodine, a 2 per cent. solution of novocaine h a little adrenalin is used to anæsthetise the skin l tissues down to the pleura, the skin being first dered insensitive by an intracutaneous injection, a point being selected slightly above the interspace where it is intended to insert the Clive Riviere needle. The skin now being insensitive, it is drawn down slightly so as to be over the selected spot, and then the needle is again inserted and pushed down gradually to the pleura, the remainder of the novocaine and adrenalin is slowly injected—2 c.cm. in all being used. The Clive Riviere needle attached to the apparatus is then dried in a spirit flame and inserted down to the pleura, the trocar is withdrawn, the tap on the needle is closed, and the cannula pushed through into the pleural space. If the clamp compressing the manometer connexion is not open it is released and the pressure changes are noted. If the cannula is in the pleura negative-pressure oscillations, varying with inspiration and respiration from 0 to −10 cm. or more, are apparent, and it is then safe to allow the air or gas to enter the pleura. The current teaching is now to introduce about 300 c.cm. at the first induction, taking careful note of the effect of this amount on the pressure readings, which are usually made a little lower, generally by about 2 cm., but which should remain negative. The needle is then withdrawn and the skin is again painted with iodine, but no dressing is necessary.

Refills and Pleural Pressures.—The sequence of the refills, the amount of air or gas introduced, and the pressures obtained are all matters requiring care, and each must be adapted to the individual case if success is to be achieved. There is no object in trying to secure rapid collapse except in dangerously severe hæmorrhage. The general rule now is only to introduce about 300 c.cm. at the induction, or such an amount as to lessen the negative pressure about 2 cm. of water. A small amount of air is less likely to cause distress to the patient, less calculated to lead to a febrile reaction from increased absorption of toxic products, and less liable to force infected secretions into other parts of the lung. If no reaction develops the first refill is generally given next day, but if there has been much rise of temperature it is well to wait till it has subsided. The amount given varies—400 c.cm. or more being introduced, or enough to lessen the negative pressure 2 or 3 cm. of water. Two days may then elapse before the second refill, three days before the third, and then longer intervals up to a week, but no definite rules can be laid down. Dr. Burrell has recently published a valuable note [4] pointing out that the object to aim at is to secure and maintain effective collapse. He tries to obtain this collapse in about a fortnight by means of five or six refills. He then endeavours to determine the optimum degree of collapse for the individual case—that is, collapse which is sufficient to keep the lesions at rest. The spacing and the amounts he determines by X ray control if possible, or by careful watching of the temperature and of the symptoms when it is not available. Refills should be given often enough to prevent the lung from re-expanding as seen by the X rays and to obviate any return of fever, or of cough and expectoration. As a rule, by the end of the first month the weekly interval may be increased to ten days, then to 14, and so on gradually to three weeks. For the remainder of the first year refills are usually necessary at intervals of three or four weeks. During the second year longer intervals may become possible, such as six weeks, and after this as long as two months. These intervals must, however, depend upon the degree of collapse and upon the rate of absorption of the gas introduced. It should be borne in mind that permitting the lung to expand by allowing too long intervals not only lessens the effectiveness of the treatment, but also tends to lead to adhesions, and thus to bring the treatment prematurely to an end. The amount it is necessary to introduce is again an individual factor and may vary from 400 to 800 or even 1000 c.cm. according to the interval, the degree of collapse, and the pressure it is desired to obtain.

[4] Brit. Med. Jour., 1924, i., 368.

The question of the intrapleural pressures to aim at is also an individual problem. There has been recently a change in the general rule in this matter. Few people now aim at securing a high positive pressure. It has been shown that effective collapse may in some cases be maintained throughout by a pressure below the atmospheric—that is to say, one still negative. On the other hand, in some cases it may be necessary to raise it considerably to secure collapse, and this may be possible without causing severe discomfort to the patient.

Selective Collapse.

The observation of cases with the X rays and the use of lower pressures have brought to light an interesting fact—viz., that in partial collapse the air introduced tends to accumulate more especially over the diseased area if this is localised and if the pleura is not adherent over it. This phenomenon is known as "selective collapse," and it is believed to be due to the changes in this area rendering it more susceptible to pressure variations. Parry Morgan some years ago suggested that this might occur, but its occurrence was established by Barlow and Kramer.[5] This selective collapse has been put forward as a plea for the use of lower pressures in pneumothorax treatment by Hennell and Stivelman. They suggest that positive pressures are only necessary where there are adhesions, a fixed mediastinum, active thick-walled cavities or extensive disease in all the lobes of the affected lung. The importance of selective collapse, which is an observation it is easy to confirm, is that it affords a hope that some form of partial collapse therapy may be practicable where there is localised disease, and that it may be possible to permit some parts of the diseased lung to function during treatment.

Bilateral Pneumothorax Treatment.

Various cautious attempts have been made to carry out this form of treatment in chronic cases with bilateral disease. Dr. Parry Morgan and a few other observers have tried it in this country, but there are insufficient data as yet to allow of an appraisal of the procedure. Barlow and Kramer[5] in America have applied the method of selective collapse to bilateral cases, and their paper is well worth study. They advise induction on the more involved side first, but if no such special reason exists, recommend that the left side should be first treated. The second side is not attempted until four or six weeks after the first side has been collapsed. The stereoscopic X ray photographs are examined after a refill to see that there is no over-inflation of this side. A few days are allowed to elapse, then 100 or 150 c.cm. are cautiously introduced into the opposite pleura and one or two refills of about the same amount are given on alternate days before the original side is again refilled. The subsequent refills depend upon the progress of the case, the effect of the inflations and degree of dyspnœa and discomfort induced. It is obvious that this form of treatment should not be tried indiscriminately, and at present it is of very limited application.

Duration and Termination of the Treatment.

The time for which the collapse treatment should be maintained is a difficult question to determine. Here, again, there can be no general rule. Most observers recommend that it should be kept up for at least three years. Saugman recommended that it should be terminated in the summer if possible, and that the treatment should be resumed if any symptoms of relapse became apparent. Most authorities advise that the expansion should be gradual, occasional refills at longer and longer intervals being given. It is important to remember in this connexion that as the lung expands adhesions usually form between the two pleural layers as they resume contact, and a premature termination of the treatment may render its subsequent employment impossible. Where an incompletely effective partial collapse only is obtained the treatment may have to be abandoned, or it may be that owing to increasing adhesions the lung slowly expands even against pressure and the pleural cavity becomes gradually obliterated. In the early stages the treatment should be carried out in a hospital, nursing home, or sanatorium, but after the disease is quiescent treatment may be continued at home, and the patient is often capable of returning to work.

Risks of Artificial Pneumothorax.

Gas Embolism.—The most important precaution is to make certain by the manometer readings that the needle is in the pleura before the gas is allowed to flow in. If the needle has not entered the pleura the readings will remain at zero or show slight oscillation if it is actually in contact with it. If the needle has entered the lung, there is sometimes a negative pressure without proper oscillations. In introducing air it is best to adjust the apparatus beforehand so that the air or gas is at the atmospheric pressure or just below it in order that the first few c.cm. may be drawn and not forced into the pleural cavity. With these precautions the risk of gas embolism is practically excluded. It is worth while to mention that gas embolism has occurred in the course of refills, so that the same strict care is necessary as for the induction.

Another risk is that common to any interference with the pleura—viz., *pleural shock*. It varies from slight faintness and anxiety to sudden and profound collapse or even immediate death. In its graver form it is fortunately rare, but it is always well to be prepared for it. Pituitrin should be at once injected, other stimulants given, hot-water bottles applied, and artificial respiration carried out if breathing has ceased. Though it has most often been observed with the primary induction, it is not unknown in connexion with refills.

Puncture of the lung may occur if there are adhesions and it gives rise to no unpleasant results unless the trocar enters a large vessel, when hæmoptysis may occur, but as a rule this is slight and soon subsides. It should also be suspected if no rise of pressure occurs after a considerable amount of air has been allowed to enter. If there are no adhesions puncture of the lung may lead to spontaneous pneumothorax and to subsequent infection of the pleura, especially if a caseous area or a cavity has been entered, when the result may be very serious. This risk is a very slight one if a Riviere needle be cautiously used for the induction.

Subcutaneous emphysema may occur, particularly if a high intrapleural pressure is produced. It is rendered less likely by the manœuvre of anæsthetising the skin over a rib above the selected interspace and drawing it down over that space when the puncture is made. It can usually be prevented from spreading by a pad and pressure over the puncture. Occasionally subpleural or mediastinal emphysema may occur, the air tracking up the cellular tissue of the neck and there spreading widely in the subcutaneous tissues. This, though unpleasant, is not serious and subsides with rest, though pain, if it occurs, may necessitate the use of morphine.

Complications During the Treatment.

Pleurisy occurs in about 50 per cent. of the cases and goes on to effusion. This is almost invariably serous unless rupture of the lung has occurred or unless the effusion becomes secondarily infected. Investigation of its cytology may show some polymorphonuclear cells in the early stages, or if secondary infection is present, but as a rule there is a marked lymphocytosis. Tubercle bacilli are often present in the fluid in very large numbers. The pleurisy is generally associated with some pyrexia which usually subsides in a few days, though occasionally it persists and is associated with progressive deterioration of the patient's condition owing to activity in the lung lesions. Before the effusion develops there may be malaise and pain. The physical signs are characteristic owing to the shifting dullness, the dead level of the fluid, and the succussion splash. The appearances in X ray examination are also striking owing

[5] American Rev. Tub., vi., 2, p. 75.

the sharp upper level of the shadow in the erect position. The fluid may be slowly absorbed or may remain for months and become converted into a greenish purulent fluid which is sterile except for the presence of tubercle bacilli. If the fluid reaches a high level some of it may be removed and replaced with air and the pressure kept at such a level as to keep the lung collapsed if possible. The patient should remain at rest in bed for some time after the temperature has subsided. Statistics show that the occurrence of simple effusion has very little effect on the end-result. Cases with effusion show nearly if not quite as good a percentage of recoveries as those without.

Purulent Effusion.—A serous effusion may become purulent if it is very chronic, and this may also occur if any marked extension of the pulmonary disease occurs. Purulent effusion may require oxygen replacement from time to time. The more severe forms of pleural infection may lead to great pleural thickening and prevent later expansion of the lung or may lead to increasing adhesion as the fluid is absorbed or withdrawn. If the fluid reaccumulates frequently the pleural cavity may be washed out with some weak antiseptic such as lysoform or with collargol.

Rupture of the lung is a very serious complication and is more likely to occur with positive pressures. It gives rise to a pyopneumothorax with a permanent pleuro-pulmonary fistula. The patients usually become acutely ill directly after the rupture and when pus has formed the pleural cavity may be washed out with antiseptic after aspiration and gas replacement. The condition is usually fatal, but thoracoplasty done in several stages has been successful in a few cases.

Pain, discomfort, and dyspnœa may occur and these may be due to mediastinal displacement. Febrile reactions of varying degree occur in some cases.

Results.

A sufficient number of statistics are now on record to demonstrate the real value of this form of treatment. It has restored to working capacity a large number of patients whose outlook apart from it was grave. It has prolonged life and given comfort to many other cases, and its value is the greater that it is applicable to cases with extensive disease provided that this is mainly unilateral.

3. METHODS OF DEALING WITH PLEURAL ADHESIONS.

The limitations imposed on the efficacy of artificial pneumothorax treatment by adhesions is strikingly emphasised by the statistics of Gravesen.[6] In 211 patients in whom this form of treatment had been attempted by Saugman and himself, he found on investigation, from three to 13 years afterwards, that in those without adhesions, thus allowing complete pneumothorax, no less than 70·2 per cent. were able to work. In cases with localised adhesions rendering the pneumothorax incomplete, only 33·3 per cent. were in this satisfactory state, while in those with more extensive adhesions, only 11·1 per cent. were capable of working. It is interesting to note that the figures for the cases with more or less complete adhesions, rendering pneumothorax impossible, are almost identical—viz., 11·8 per cent.; in other words, artificial pneumothorax is useless where adhesions are widespread.

It was to be expected that these failures would lead to a careful study of the character of adhesions and would stimulate attempts to deal with them. Investigation of X ray photographs, especially of stereo-radiograms, in cases of incomplete artificial pneumothorax reveals the fact that not a few adhesions are string- or band-like in character, others being membranous, while both may be capable of stretching. They can often be seen to drag on the lung and prevent it from collapsing completely. A third kind is the extensive surface adhesion commonly seen at the apex or at the base. This variety, if at all widespread, practically excludes the possibility of artificial pneumothorax treatment, since it is usually over the diseased part of the lung, and it is impracticable or risky to strip up such adhesions surgically.

Attempts have been made to deal with the string- and band-like or membranous adhesions by four different methods. (1) By increased intrapleural pressure. This may be effective on small or recent adhesions, but it is not devoid of risk if high positive pressures are employed. Not only may they cause pain, tightness, and dyspnœa, but there is also the risk of rupture of the lung with subsequent pyopneumothorax. Moreover, a mediastinal bulge or hernia may occur and increase in pressure may even lead to its rupture rather than to stretching or tearing of the adhesion. (2) By introducing a special tenotome through the chest wall, under careful local anæsthesia, and cutting the adhesion under control of the X rays, the adhesion being rendered taut by suitable increase of pressure of the intrapleural gas (Morriston Davies). The uncertainty of this method and the risk of hæmorrhage render it unsuitable for general use. (3) In more extensive adhesions the pleura has been opened through an intercostal space to allow of the adhesions being ligatured and cut. Post-operative hæmorrhage and empyema have been observed after this method and it seems to involve more risks than are commensurate with its advantages. (4) The procedure introduced by Jacobaeus seems the method of choice where practicable. A thoracoscope made on the principle of a cystoscope is introduced into the pneumothorax cavity through a cannula inserted usually in the posterior axillary line, the position chosen being that most convenient for observation of the adhesions. If these seem suitable for division a galvano-cautery is introduced through a second cannula, which has been inserted through an intercostal space in such a position as best to allow of dealing with the adhesions. This is usually in the anterior axillary line in the seventh, eighth, or ninth space for adhesions high up, or in a lower space for those near the diaphragm. The development of smoke in the pleural cavity may delay the completion of the operation, but can usually be dealt with satisfactorily. Jacobaeus has been successful in 75 per cent. of his cases, while Holmboe[7] and Gravesen [8] report favourably of its use. Piguet and Giraud [9] at Leysin write enthusiastically of its value, and it has been employed in several cases in this country. The operation can be done under local anæsthesia, and the risks involved are not serious if due precautions are taken. They comprise (1) hæmorrhage, which is usually avoided by using the cautery at a dull-red heat. (2) The lung may be opened owing to pulmonary tissue being prolonged into the adhesion by traction. If a cavity be opened in this manner it may lead to pyopneumothorax. This can usually be avoided by dividing the adhesion as near the chest wall as possible. (3) Pleural effusion sometimes results, but as in ordinary artificial pneumothorax cases, it does not, as a rule, interfere with the satisfactory progress of the case. (4) Surgical emphysema and temporary fistulæ may result from the puncture wounds, but are not serious. The method should be strictly limited to cases with string- and band-like adhesions, and a severe selection should be exercised as to the suitability of these. It is probable, therefore, that the number of cases to which it can be applied will be comparatively few. None the less, in experienced hands it represents a real addition to our means of treatment and we should carefully consider it in certain cases.

4. PHRENICOTOMY.

Theoretically section of the phrenic nerve on the affected side might be expected to be of value in securing rest to the lung, and it is claimed by some that this procedure alone reduces the lung capacity on that side by a quarter to a third, and that its effects persist for from six to nine months. Opinions differ

[6] Brit. Med. Jour., 1923, ii., 506.

[7] Tubercle, 1919, i., 1.
[8] Brit. Med. Jour., 1923, ii., 506.
[9] La Presse Médicale, 1923, i., 266.

as to its practical value by itself. It has been recommended in cases with adhesions of the base of the lung to the diaphragm, particularly those associated with cough. Mr. Morriston Davies has also found section of the left phrenic useful in left-sided cases associated with vomiting after cough. Phrenicotomy has also been employed in conjunction with other methods of treatment, notably pneumothorax, pneumolysis, and thoracoplasty. It seems worthy of more extended trial than it has yet received. The continuity of the nerve path may be severed by section, resection of a piece of its length, crushing, or by alcohol injection.

5. EXTRAPLEURAL PNEUMOLYSIS.

As long ago as 1892 Tuffier suggested that the diseased part of the lung might be allowed to collapse by stripping the pleura from the endothoracic fascia. This operation, to which the name of extrapleural pneumolysis has been applied, is easily effected by an incision through an intercostal space, and it has had a certain vogue since 1910. The real difficulty is the filling up of the extrapleural space left by the collapse of the lung. Attempts have been made to keep up an extrapleural pneumothorax by air injections. This often fails owing to the difficulty of retaining the air or to the accumulation of serous exudate which may become infected. More success has been obtained with fat grafts obtained from the subcutaneous tissue, omentum, breast, or from lipomata. Muscle has been used, small rubber balloons, and paraffin, but though some cases have been successful, there are many failures, either due to infection of the cavity left or to the formation of serous exudates leading to extrusion of the substance used for packing.

Separation of adhesions over the apical region only is referred to as apicolysis. Some surgeons, notably Bull of Christiania, perform apicolysis in the course of the operation of thoracoplasty after removing part of the third or fourth rib, and before dealing with the second and first ribs. On the whole, it seems that pneumolysis has given rather disappointing results, except in those where local pneumolysis has been aided by adequate fat grafts.

6. THORACOPLASTY.

There remains now for consideration the most effective of all the surgical methods of dealing with cases in which artificial pneumothorax fails or is impracticable owing to adhesions—viz., extrapleural thoracoplasty, which in its complete form consists in removal of segments of all the ribs from the eleventh or tenth to the first. It appears to have been first suggested in 1885 by Cérenville, and independently by Spengler. After 1907 the suggestion was taken up and developed by German surgeons, notably Brauer, Friedrich, Wilms, and Sauerbruch. The method was adopted and applied by Scandinavian surgeons soon afterwards. It received until recently little recognition in this country, except by Morriston Davies and Roquette, and it was looked on with disfavour in France, owing to its severity and mutilating character. In both countries it is now achieving tardy recognition. Two valuable papers on its technique and the indications for its employment have recently appeared in France by Profs. Bérard and Lenormant.[10]

Indications.—In general it may be stated that thoracoplasty is indicated in cases suitable for pneumothorax treatment in which that form of treatment is impracticable or has failed owing to pleural adhesions, but it should never be employed in such cases till the latter has been attempted. It must be remembered that even a complete thoracoplasty does not give more than three-quarters of the collapse of the lung afforded by a complete pneumothorax. Lenormant suggests that thoracoplasty is preferable to pneumothorax in cases with fistulous tuberculous lesions, either pleuro-pulmonary or pleuro-parietal, and also in cases with basal excavation, in which a partial thoracoplasty may suffice. It may also be considered in cases of severe recurrent hæmorrhage in which pneumothorax has failed.

The *contra-indications* are also practically those of artificial pneumothorax therapy, but the age limitations are more marked.

In coming to a decision as to its adoption in any given case a stricter standard as to the condition of the opposite lung and as to the general condition of the patient than that for artificial pneumothorax must be adopted and great attention paid to the condition revealed by X ray examination. Stereoscopic radiograms should be obtained if possible. A further point to bear in mind is that thoracoplasty throws the lung permanently out of action, unlike artificial pneumothorax, which can be stopped, allowing the lung to expand and re-function.

Methods.—(1) The original Brauer-Friedrich operation, a development of Schede's operation for empyema, consisted of a large curved incision from near the sternum below the clavicle down to the tenth rib and up to the level of the second dorsal spine behind. It allowed of extensive removal of all the ribs from the first to the tenth. It proved too severe for general use and was associated with a heavy early mortality. (2) The "pillar resection" or rib mobilisation of Wilms was introduced in 1911. It was a two-stage operation with an interval of three or four weeks. At the first, small pieces of the posterior part of the first seven or eight ribs were removed, while at the second, pieces of the anterior ends or of the rib cartilages of the first six were cut away. This, as a rule, gave insufficient collapse and both it and the Brauer-Friedrich operations are now discarded and are chiefly of historical interest. (3) The third form is that generally employed at the present time. It was introduced by Sauerbruch and adopted by Saugman, who did much to popularise it. A long hooked paravertebral incision is made, its lower end curving along the tenth rib to the posterior axillary line. The ribs are exposed by cutting through the muscles and drawing the scapula out of the way. Sections of the ribs from the tenth to the first are excised. Three centimetres or more of the first rib should be removed if possible. The amounts increase to the seventh or eighth and lessen to the tenth, but may increase progressively to this rib. A part of the eleventh may be taken, but it is better to leave it if possible as there is less likelihood of "diaphragmatic flutter." A point of great importance is that the place of section posteriorly should be as near the transverse process of the vertebra as possible. A total of 120 to 150 cm. of rib may be removed. The question as to whether the operation should be done in one or two stages, and as to the choice of anæsthetic, are matters of technique which vary with different operators. The general tendency is towards the two-stage form and the mortality of this is less. It is noteworthy that more and more surgeons are coming to employ general anæsthesia, usually gas and oxygen, combined with local anæsthesia to lessen shock.

Great care is necessary in the preparation of the patient for operation. He should be rested in bed and appropriate treatment directed to the circulatory and digestive systems, including the administration of sugar. Cough may be promoted shortly before the operation if there are cavities. Morphine or omnopon and atropine are usually given just before the anæsthetic. The after-treatment is even more important. Firm strapping and support during cough are essential to promote collapse and obviate "mediastinal flutter" or flapping movement of the mediastinum with respiration. Pain is often a distressing feature and may require analgesic drugs. Some surgeons claim that alcohol injection of the intercostal nerves during the operation obviates this. Dyspnœa is not infrequent but soon subsides. Digitalis, camphor, adrenalin, and oxygen may be used when necessary. A febrile reaction is common during the first few days after the operation. Bull's observations tend to confirm the general opinion that this is due to increased absorption of toxins owing to the disturbance and collapse of the lung. After healing some form of

[10] Journal de Chirurgie, xxii., 3, pp. 225 and 240.

corset support or bandage is worn, and if the patient is afebrile, exercises are devised to restore movements of the arm, which are usually at first limited. The patient should undergo a period of sanatorium treatment.

Risks of the Operation.—The immediate risks are those of shock, exhaustion, and wound infection, but the immediate mortality of the operation in experienced hands seems to be small, even as low as 2–4 per cent. The total mortality in the Scandinavian statistics is about 10 per cent., including the earlier cases. The later operative mortality is chiefly due to aspiration pneumonia, or to the spread of the disease in the opposite lung. The mortality is much greater in right-sided than in left-sided cases.

Results.—The recorded results are naturally somewhat varied. Of Saugman and Gravesen's 69 cases, 31, or 44·9 per cent., were fit for work at periods of from two to seven years after operation. In Bull's cases the number of cures after three years' observation amounts to one-third. Brauer's figures are very similar; recovery occurred in about 30 per cent., and in another 30 per cent. there was considerable improvement, while in 10 or 15 per cent. the disease progressed in the opposite lung. Thoracoplasty must therefore be admitted to have a useful place in treatment, but in view of its severity and of the fact that its effects are permanent, great care must be exercised in its application.

Modifications.—Various modifications of the original method are employed. A partial thoracoplasty is sometimes carried out for localised disease, either with or without pneumothorax, and it is sometimes recommended to cut the phrenic nerve shortly before the operation.

7. Other Surgical Measures.

The operation of lobectomy or excision of the diseased part of the lung is no longer employed in this disease. Ligature of a branch of the pulmonary artery has been carried out in hæmorrhagic cases and as a means of inducing fibrosis in a lower lobe. This operation is also now practically discarded. The treatment of the surgical complications of pulmonary tuberculosis such as fistula, tuberculosis of the epididymis, kidney, glands, and spine, are all matters in which we have to invoke the aid of the surgeon. The question as to the advisability of operation in such cases largely depends upon the stage of the pulmonary disease. Only operations of urgency or of necessity should be undertaken in patients with quiescent tuberculous disease, since general anæsthesia seems not infrequently to activate dormant lesions. Wherever possible operations should be done under local or spinal anæsthesia. At the same time, the experience of thoracoplasty proves that patients with active disease can take general anæsthetics such as gas and oxygen without undue risk.

8. Rôle of Surgery in the Treatment of Pulmonary Tuberculosis.

The boundary zone where medicine and surgery meet is a fascinating territory to explore, but one with pitfalls. In the surgery of the stomach, duodenum, gall-bladder, appendix, and bowel, the most dramatic results are obtained in cases in which medicine has failed most lamentably. The surgery of pulmonary tuberculosis promises to give like results, but it should be clearly recognised that surgery in this disease is not, and cannot be, a substitute for medical measures, but that it may be a valuable adjunct. This branch of surgery, perhaps more than any other, demands an understanding between the physician and the surgeon and a knowledge on the part of the surgeon of the medical problems involved to a greater extent than any other. The operation carried out must be devised to meet the needs of the individual patient. Surgery cannot here be the first line of attack, but it can be a very helpful aid. We may hope that a truer perspective will obtain here than was the case in the early days of gastric surgery.

Conclusion.

It is now my duty to express my thanks to my friends and colleagues who have helped me in preparing these lectures, particularly to Dr. R. C. Wingfield, who has helped me in many ways and lent me the radiograms and photographs I have shown; to Mr. A. Tudor Edwards for his criticism and advice in regard to the operative procedures; and to Dr. D. E. Bedford for assistance in looking out references. Lastly, I have to express to yourself and the Council of this Society my appreciation of the honour you have done me in asking me to deliver these lectures, an honour as gratifying as it was unexpected. Although I feel that I owe this distinction to my association with the two hospitals in which I worked as a student and which it is now my privilege to serve, my pleasure is none the less great. Though I have not been able to present anything new or dramatic, I like to think that my choice of subject at least would have been agreeable to the distinguished physician and philanthropist whose memory we commemorate in these annual lectures. In his "Hints for the Establishment of a Medical Society in London" he wrote: "The principal part of our knowledge must be ever derived from comparing our own observations with those of others." This I have tried to do in regard to this disease, and in preparing this review of the methods of treatment now in use, I at least have been greatly the gainer.

From the Royal School of Medicine, Cairo.

THE INCIDENCE OF CANCER IN EGYPT.

An Analysis of 671 Cases.

By ROBERT V. DOLBEY, M.S. Lond., F.R.C.S. Eng.,
DIRECTOR OF THE SURGICAL UNIT; SURGEON TO THE KASR-EL-AINY HOSPITAL, CAIRO;
AND
A. W. MOORO, F.R.C.S. Eng.,
SURGICAL REGISTRAR AND TUTOR TO THE HOSPITAL.

An inquiry into the incidence of cancer and malignant disease in general, in Egypt, will help to throw some light upon the history, ætiology, and probable causation of this disease. Not only are we dealing with a population of an entirely different race from any in Europe, but we have also a considerable admixture of the Negroid and Negro-Arab to consider. The diet of the population, and, above all, the prevalence of parasitic disease in the country, are of value in the consideration of the relation of malignant conditions to diet and to parasitic disease. Ninety per cent. of the fellaheen or country people of Egypt probably suffer at one time or another from bilharzia, ankylostoma, and ascaris, or a combination of all three. There is now statistical evidence that the picked men of the fellaheen population who enter the army or the police are infected with these three diseases to the extent of 85 per cent. The more cosmopolitan urban population of Egypt, which numbers about 20 per cent. of the whole, is much less uniformly affected.

The habits and customs of the people are also utterly different from those of England or America, but in spite of these differences and, particularly, of the amount of parasitic disease, the total number of cases of malignant disease in proportion to population is probably very much less than in England. There are no complete statistics; but the comparison of the number of cases attending the main hospital of Egypt with those attending a general hospital of the same size in London gives us this impression. But if the total amount is less, the incidence and anatomical distribution of cancer is entirely different in Egypt from that of more temperate regions. In the first place, the incidence among the various races and racial elements in Egypt appears to be strictly in accordance with the racial proportion in

the population. The Negro from the Sudan with woolly hair and coal-black skin, and the Berberine, a Negro-Arab, with less pigment in his skin and less kink in his hair, are as often affected as the brown-skinned flat-black-haired Egyptian, or even the fair Turk and Armenian. Our experience of cancer in negroid peoples seems, therefore, to be different from that of other observers.

Incidence of Disease from Hospital Figures.

We have analysed all the cases of cancer and malignant disease (671) that have attended this (Kasr-el-Ainy) hospital in the last four years. This hospital has 400 available surgical beds, a yearly in-patient population of 13,000, and a yearly out-patient attendance of 122,000, drawing patients from the whole of Egypt. Thus it reflects the comparative incidence of disease in the whole country.

Epithelioma of the scalp is definitely more common than in England or America (30 cases). An explanation for this may be found in the habit of shaving the head, the great incidence of favus and other irritating skin conditions, and the intensity of the actinic rays of the sun. Sarcoma of the flat bones of the skull is also definitely more common (10 cases); this is in accord with the great prevalence of sarcomata of the long bones (49 cases), and of the bones of the face, especially of the upper and lower jaws (23 and 16 cases respectively). Myelomas of the long bones, the jaws and clavicles, are in proportion to the prevalence of periosteal and endosteal sarcomata. The malignancy of sarcoma of the long bones is not so great, however; gland involvement and metastatic growths are late and comparatively rare. There are a large number of cases in which a general cachexia or sepsis has killed before secondary deposits have occurred. This is, in our opinion, a very marked feature of Egyptian sarcoma and of cancer. Melanotic sarcoma is rare, possibly owing to the general distribution of pigment and to the absence of scattered areas of pigment, as moles and freckles, among our people.

Rodent ulcer (41 cases) is a very common condition in Egypt. It presents no unusual features, and may be attributable to the exposure of the fellaheen to sun in their field work. The region of the orbit is most commonly affected. Malignant epulis is probably not more common than elsewhere; but there is a very common condition of epithelioma of the lower jaw that is entirely different in its onset and its development from any in our experience elsewhere. This disease commences in the alveolar margin of a tooth that is intrinsically healthy, but has a marked deposit of tartar and food débris at the junction of tooth and alveolar margin. In this respect it is essential to say that, except among the more leisured classes, there is no system of brushing teeth in Egypt, not even with a twig or piece of wood as is the case in the Far East. Egyptian adult teeth of the labouring classes, though, as a rule, free from caries, are yet filthy in that there are gross collections of tartar and food débris at the neck of the teeth, and in very many cases the gums are swollen, septic, and inflamed. True cases of pyorrhœa are not uncommon. It is also interesting to observe the prevalence of true dental caries and alveolar abscesses in the jaws of Predynastic, Dynastic, and Ptolemaic Egypt. Through all the ages from 2000 years B.C. the dental treatment of ancient Egypt was deplorable. Whenever the pulp cavity of an ancient Egyptian tooth had been exposed an abscess had formed, and no attempt apparently been made to extract even the most decayed teeth. They are left in situ with all the evidences of years of abscess formation and new inflammatory bone.

The epitheliomatous conditions of the jaws in modern Egypt, as referred to above, are remarkable for the rapidity of their development, the uniform commencement in the alveolus of a tooth, the rapid separation of a sequestrum of the whole thickness of the alveolus carrying from two to six teeth; and, finally, the often complete absence of glandular involvement even in the submaxillary region. Were it not for the histological appearances one would look upon this condition as a septic osteomyelitis of the jaw. Death occurs from aspiration pneumonia, and not, as one would expect, from hæmorrhage from the vessels of the floor of the mouth.

Cancer of the Lip, Tongue, and Œsophagus.

Cancer of the lip is not common (31 cases). There appears to be no relation between this form of cancer and smoking. Tobacco is smoked, as a rule, by the country people by bubbling the smoke through water in a "hookah," the mouthpiece of which is of smooth and polished amber, or by rolled cigarettes. The young urban population, however, and the leisured classes of Egypt now affect the cigarette, but they exhibit a much less marked tendency to lip cancer than the fellaheen who work in the sun all day.

Cancer of the tongue is not common (25 cases), and is characterised by special features. It has a slow development; it is not associated with evidences of syphilis; glandular involvement is very late indeed even in the submaxillary region, and death from secondary hæmorrhage from the lingual or carotid vessels comparatively unknown. We have never seen cancer of the tongue develop in any but a very septic mouth; nor have we been able to discover in Egypt any cases of the typical chronic superficial glossitis of that organ or any evidences of gross tertiary syphilis in connexion with tongue cancer. Tooth plates and artificial dentures are not indulged in by the fellaheen. Death in cancer of the tongue is usually a result of aspiration broncho-pneumonia.

Cancer of the œsophagus is very rare (six cases). The operation of gastrostomy for pharyngeal and œsophageal cancer has only been performed three times in five years. Malignant disease, intrinsic or extrinsic, of the larynx is much more common (29 cases). Tonsillar cancer is almost unknown. No case of chloroma in children has been observed during the last five years.

Cancer of Breast and Cervix.

Cancer of the breast (75 cases) presents no unusual features in its incidence, type, or development from that observed elsewhere. It is sometimes difficult to determine the age-factor, as many of the fellaheen do not know their true ages. Breast-feeding among babies is common up to two or three years. To wean a child before that time is almost tantamount to a death sentence. Feeding-bottles are, in Egypt, fatal to babies; but fortunately they are rarely used among the country people. Wet-nurses are the rule. Many mothers develop acute mastitis and mammary abscesses. We gather the impression that cancer of the breast is more commonly of the rapidly growing encephaloid variety, and that fungation is perhaps more common in Egypt than in England or America. But this may be owing to the fact that cases of breast cancer seldom come to hospital in any but an inoperable condition. Two cases only of fibro-adenoma or simple tumour of the breast have occurred in this period of three years, although careful search for this condition has been made in all our women patients. Nor have any cases of chronic interstitial mastitis, with or without cystic degeneration, been observed. This appears to negative any causal relation between the degenerative changes in the involuting breast of the woman of 40 and the development of cancer.

Cancer of the cervix (19 cases) and of the body (six cases) of the uterus does not appear to differ in appearance or type from that observed elsewhere. It is, however, a very much rarer condition in Egypt than in England or America. These cases arrive usually in an inoperable state. As the vast majority of our women are married and have borne children we can draw no conclusions in regard to the influence of pregnancy upon malignant conditions of the breast or uterus.

Cancer of Digestive Tract.

It is in the digestive tract that the incidence of cancer is most remarkable. There is practically no cancer of the stomach in Egypt, only eight cases in three years; and, as there is also very little gastric ulcer, six cases in the same period, there appears to be a definite causal relationship in a negative way between the two conditions. Secondary cancer of the liver, as one would expect, is rare (four cases); but primary cancer originating in the gall-bladder and the gall-bladder fissure of the liver is much more common (ten cases). As the incidence of gall-stones in Egypt, six cases in this period of three years, is negligible, in spite of the fact that typhoid fever is endemic, there does not appear to be any connexion between gall-stones and the development of carcinoma of the gall-bladder.

In the large intestine, again, cancer is very rare in spite of the universal parasitic infection of the colon, and, especially, the prevalence of bilharzial growths and papillomata. These do not appear to present any tendency to malignant development. Cancer of the rectum (seven cases) is comparatively rare, notwithstanding that it is the most common site for bilharzial papillomata and growths with the consequent irritation of the lateral-spined ova of this parasite.

In the urinary bladder, however, the incidence of malignant disease, both carcinoma and sarcoma, as a sequel to the irritation of the terminal-spined bilharzia ova in the foul and alkaline bladders of cystitis is extremely common (51 cases). But we know of no cases of epithelioma of the kidney pelvis or of the ureters, in spite of the common infection of the whole urinary tract with bilharziasis. We believe that the alkalinity and sepsis of an inflamed bilharzial bladder is partly responsible for the development of carcinoma in that organ. We have seen no cases of the development of cancer in a non-inflamed bilharzial bladder. The large intestine is even more exposed than the bladder to the irritation of parasites, but the reaction of the contents of the bowel is usually acid, and chronic sepsis, such as is found in cystitis, is not present.

Malignant conditions of the kidney, including hypernephroma, are also extremely rare. The prostate, however, is a very common seat of cancer, but simple enlargement of that organ is much less frequent than in England or America. There are very seldom indeed any cases of chronic prostatitis or gleet among the fellaheen. Early marriage seems to be responsible for the non-development of both these conditions, though, we must admit, the severity and complications of gonorrhœa among Egyptians are much less marked than in Europeans resident in Egypt. Gonorrhœal and syphilitic infections contracted from the same source, for example, a Levantine woman, are infinitely more severe in a Northern European than in an Egyptian. There can be no acquired immunity to syphilis of very long standing, for there are no evidences of syphilis in the bones of Predynastic, Dynastic, or Ptolemaic Egypt. It is probable that cancer of the prostate is usually an extension of the disease commencing in the trigones of the bladder from pre-existing bilharziasis.

Cerebral Tumour.

Cerebral tumour is comparatively very rare in Egypt (11 cases). Ancient Egyptian skulls show definite evidences of malignant conditions; but in the majority of cases these appear to be extensions from epitheliomata of the scalp or from rodent ulcer of the face. Malignant disease of the thyroid gland is not uncommon (15 cases). As a primary growth it is not associated with disorder of function of that gland; but in two cases where there were secondary deposits of breast cancer in the thyroid gland there were marked evidences of hyperthyroidism. In this connexion it is interesting to observe that although there are a large number of cases of simple parenchymatous goitre, adenomata and cysts (122 cases), in Egypt we practically never see a case of exophthalmic goitre or of cretinism among the country people (one case of each in three years).

Diet of the Egyptians.

The diet of the fellaheen who comprise 80 per cent. of the population of the country is almost entirely vegetarian. Meat is usually eaten once a week only; and goat or mutton is the meat of choice. Swine flesh, as in all Moslem countries, is forbidden. So is alcohol in any of its forms. Cheese, milk, eggs, and beans form a large proportion of the daily diet. The green tops and roots of vegetables, such as radishes, are constituents of nearly every meal. Potatoes are not grown in Egypt, and are only eaten in the towns. Expectant mothers and lying-in women eat chicken for two weeks. As a rule the pigeons and chickens are sent into the towns to be sold.

Pigeons are kept chiefly for the value of their guano in growing melons. Tomatoes form a large ingredient of the common food. Onions, as would be expected, are a constant feature of every day diet. Fruits, with the exception of dates, fresh figs, apricots, and, especially, water melons are not commonly eaten except in the summer months. There is no method of preservation of food by smoking, salting, or drying in the sun, or by any chemical means. Nor is frozen or chilled meat ever eaten by the vast majority of the people. On the occasions of ceremonial feasts a large amount of animal food is eaten. This chiefly consists of mutton or goat, chickens and turkeys; but the average diet of 70 per cent. of the people for six days of the week is eggs and cheese and herbs, onions, beans, tomatoes, unleavened bread, and the green tops of vegetables, especially of the radish family.

But it is interesting to observe that, in the towns where the Egyptian people, often of the more leisured classes, have adopted European habits of food and cooking they have acquired European diseases. Egyptians of the richer classes of society, whose inclination or work keeps them in the cosmopolitan towns, do develop gastric and duodenal ulcer, gall-stones, and appendicitis, and with the development of these surgical aspects of gastro-enteritis also comes a predisposition to gastric and intestinal cancer, conditions which are almost unknown to their simpler compatriots in the country districts.

Conclusions.

It may be objected that the experience of one hospital is no true criterion of the incidence of malignant disease in a whole country. But we can rightly claim that Kasr-el-Ainy is the great medical and surgical court of appeal for the whole of Egypt. We draw from the whole of the Nile valley; and we are peculiarly situated so as to obtain as clear a view upon the prevalence of malignant disease as the absence of full statistical evidence will allow.

The conclusions to which we have come as a result of our daily work and the examination of these cases are these:—

1. The incidence of cancer among Negroes is not essentially different from that of Negroid, Negro-Arab, or the Egyptian races.

2. There is no causal relationship between cancer and parasitic diseases. It appears to be merely the irritation of the parasites and their ova and embryos and the coincident chronic sepsis which is responsible. But the incidence of cancer in relation to bilharzia of the bladder suggests that, only in an alkaline-infected medium such as the stagnant urine of cystitis in bilharzial bladders, does the irritation of ova produce cancerous changes. In the renal pelvis, the ureter, and the intestinal canal the incidence of parasitic disease is almost as great as in the bladder, and yet the development of cancer is almost unknown.

3. There seems to be no connexion between cancer of the tongue and syphilis.

4. Malignant disease affecting the bones, the skin, and skin appendages appears to be definitely more common than in Europe or America, and may be attributed, as far as the skin is concerned, to the actinic rays of the sun of Egypt.

5. There is a definite relationship, from a negative point of view apparently, between the incidence of gastric ulcer and gastric cancer.

6. There is no relation, presumably, between gall-stones and cancer of the gall-bladder or the gall-bladder fissure of the liver. Nor is typhoid fever, in Egypt, a predisposing factor in the production of gall-stones.

7. The comparative incidence of cancer of the uterus and breast in married and unmarried women does not allow of any statistical conclusions to be drawn, in Egypt, where the vast majority of all women have been married very early, usually some time before 20 years, and have borne children. The comparative absence of non-malignant conditions of the breast, such as fibro-adenoma, and, especially, chronic interstitial mastitis of the involuting breast, with or without cystic degeneration, is remarkable and inexplicable. The latter state is looked upon by some pathologists as a precancerous condition; but our experience in Egypt seems entirely to negative any relation whatever between chronic interstitial mastitis, which is practically unknown, and cancer of the breast, the incidence of which is probably the same in proportion as in Europe.

8. The progress and development of individual cases of cancer is definitely different in Egypt from that of England or America. The progress is, as a rule, less rapid, the involvement of glands less marked, and the development of metastases more infrequent. There appears also to be a form of epithelioma of the alveolar margin of the jaw that exhibits most unusual features (vide supra).

9. There appears to be some definite relation between cancer and diet. Simple vegetable foods, the absence of preserved, chilled, or frozen meat of any kind, the lack of jams or fruit preserved in sugar, and the complete avoidance of alcohol in any of its forms seem to be consistent with the non-development of cancer of the intestinal tract. While the adoption of European foods, alcohol, and preservatives by the same people in the cosmopolitan atmosphere of towns definitely appears to be responsible for gastric and duodenal ulcer, gall-stones, appendicitis, and cancer of the digestive tract.

10. The almost complete absence of functional nervous disease among the simple fellaheen, and, indeed, of organic disease of the nervous system also, has, we consider, a most important bearing on the development of cancer in Egypt. For diet alone will not serve to explain the incidence of cancer. Nor can the use or abuse of alcohol or tobacco be called upon to account for the discrepancy between Egyptian and European cancer. The whole of pagan Africa seems to have learned how to ferment corn as soon as it learnt how to grow it, though the use of alcohol, in the form of native beer or spirit, was usually reserved for ceremonial occasions. But the incidence of cancer appears to be the same in the pagan African from the Southern Sudan as in the non-alcoholic Moslem Arab or Egyptian.

One great and compelling cause for the distribution and incidence of cancer lies, we believe, in the relative freedom of the fellaheen of Egypt from nervous diseases, functional or organic. This also serves to explain the absence of exophthalmic goitre or cretinism in a country where simple goitre is so common. It also explains many of the other contradictions in the surgery of Egypt. The industrial revolution of the nineteenth century has passed Egypt by. Rural Egypt has hardly changed in 3000 years. The internal-combustion engine, the bicycle, the sewing machine, electricity, the telephone, the daily paper, the printing press, or wireless telegraphy have not happened as far as the majority of the fellaheen are concerned, for 75 per cent. of them cannot read or write. None of these advances in civilisation have altered their lives to any great degree. The only obvious change in the life of the fellaheen in 3000 years, probably, lies in the substitution of paraffin as an illuminant for the primitive bean oil. There is an absence of financial stress and strain, though there is great poverty. The Egyptian fellah, and he forms 80 per cent. of the population, puts his savings into such objective and solid investments as land and cattle. For him there are few uncertainties in regard to seasons. The Nile flood has taken all worry and anxiety from him in that respect. His buffalo is immune to cattle plague as it is, relatively, to tubercle. To each fellah is his reward according to his toil. Money to him does not represent a source of credit or even a medium of exchange; it is an object in itself to hoard or to bury, but never to lend at usury. Stocks and shares and cotton futures mean nothing to him. So the wear and tear and nervous strain of modern twentieth-century life do not affect him. There is very much more, in all probability, than an accidental relationship between the almost complete absence of functional nervous disease and hysteria among the fellaheen and the rarity of abdominal cancer, of symptomatic enteroptosis, of mucous colitis, and the whole train of subjective nervous phenomena which Arbuthnot Lane embraces under the heading of intestinal stasis.

The psychology of Egypt is totally different from that of England or America as a whole. There are no suppressed emotions or complexes in the Near East or the Mediterranean littoral; no need for psycho-analysis. In the presence of death, grief is overwhelming. Mourners tear their clothes and hair, wring their hands, and express their sense of loss in torrents of tears. Fear expresses itself in terms of panic-stricken flight, religion in wide-eyed frenzy and fanaticism on occasion. There is no reserve, no disciplined dry-eyed suffering, though there is a fine dignity in the Orient; no stoicism, though there is an admirable endurance of pain. We have no gastric invalids in Egypt, no nervous dyspepsias, no hypochondriacs, no valetudinarians, except among the student and leisured classes; and that is perhaps why we have, comparatively, no gastric ulcer, no gall-stones, no appendicitis, and no gastric cancer.

AN UNEXPLAINED DIAZO-COLOUR-REACTION IN URÆMIC SERA.

BY C. H. ANDREWES, M.D., M.R.C.P. LOND.,
LAWRENCE SCHOLAR, ST. BARTHOLOMEW'S HOSPITAL.

(From the Wards and Laboratories of the Professorial Medical Unit, St. Bartholomew's Hospital.)

THERE have been numerous recent studies in the literature, especially in Germany, on Hymans van den Bergh's application of Ehrlich's diazo-reaction to the study of bilirubin in the blood-serum. The technique of this test has been described in this country by McNee.[3 4] Briefly, it consists of the addition of a freshly made mixture of diazotised sulphanilic acid and sodium nitrite to the serum; a pink colour due to azo-bilirubin may appear either at once (direct reaction); or only in alcoholic solution, after removal of the protein (indirect reaction).

I have lately studied this test in 184 patients, mostly suffering from jaundice or some condition affecting the liver. The series included, however, "controls" suffering from other diseases; and it is with 16 patients suffering from nephritis that this note deals. It was found in performing the indirect test (in alcoholic solution) on the serum of certain of these patients that an orange-buff colour appeared. This gradually deepened over a period of 24 hours. At the end of this time it seemed possible that the

colour was due to azo-bilirubin "gone wrong"; so the solution was made alkaline, in order to test for the green colour which azo-bilirubin has in alkaline solution. Quite unexpectedly a beautiful cherry-pink colour appeared, and after lasting for a few minutes faded away. Similar results were obtained in at least eight patients with uræmia, and in no other patient. It was specifically looked for in at least 22 other patients suffering from various diseases. I can find no reference to this colour-reaction in the literature.

The characters of the reaction are as follows: The colour differs from that given by bilirubin (1) in being buff instead of pink; (2) in coming very slowly, even in the presence of alcohol; (3) in turning pink instead of green on being made alkaline. The reaction does not take place satisfactorily in aqueous solution. The buff colour begins to appear in a few minutes and its rate of development is proportional to the depth of colour ultimately reached. The pink colour is brought out on adding alkali after 24 hours, or earlier if the buff colour is very deep. Caustic soda must be the alkali used; ammonia and sodium carbonate do not cause a good pink to appear. The pink colour persists for from a few seconds to over half an hour; the deeper it is the longer it lasts. Some nephritic sera give a faint buff colour but no pink on adding alkali, perhaps because the substance is too dilute.

Clinical Aspect of the Reaction.

The table of the clinical results shows that it occurred only in patients with severe uræmia; all those giving it had at least 220 mg. of urea per 100 c.cm. in their blood. Their uræmia was due to varying causes—hydronephrosis, polycystic disease, contracted red kidneys, contracted white kidneys. A positive result was not necessarily associated with twitching or convulsions; in other words, it occurred in any of the clinical types of uræmia.

Table showing Clinical Results.

Comment.

Case 1.—Heart failure + nephritis.
Case 2.—Gout. Hepatic cirrhosis.
Case 4.—? Yellow conjunctivæ on admission.
Case 6.—Polycystic kidneys.
Case 8.—Rose Bradford kidneys.
Case 9.—More chloride than nitrogen retention.
Case 10.—Pyelonephritis.
Case 11.—Acute arthritis and pericarditis (rheumatic ?) with interstitial nephritis. No symptoms of uræmia.
Case 12.—Enlarged prostate.
Case 14.—Double hydronephrosis.
Case 15.—Small red kidneys.

It will be seen that patients dying of definite uræmia always showed this reaction. Case 11 did not show it and clinically appeared to be dying more of her acute infection than of failure of renal function. In some patients, such as Case 6 on two occasions, and Case 11 on one occasion, the yellow buff colour appeared, but no pink on alkalinising. The diazo-reagent, if left overnight, goes yellow by itself (but not pink on being made alkaline later). While I do not think this has any bearing on the colours obtained, I have refrained from laying any stress on a colour which did not go pink on subsequently adding alkali. Normal sera give a yellowish colour with the diazo-reagent in alkaline solution; the buff colour of the reaction described above develops in acid or neutral solution.

Results of Other Workers.

Van den Bergh [5] found that a hypobilirubinæmia was the rule in nephritis. I was able to confirm this; in the table above, the title "subnormal" means that there was too little bilirubin in the serum for accurate measurement. Feigl and Querner [2] found that there was usually very little bilirubin in the serum unless there was heart failure as well. Beth [1] considers that bilirubinæmia is an important diagnostic point between malignant nephrosclerosis and chronic nephritis. In the first case he finds a bilirubin value above normal; in the second case, little or none.

Problem of Causation of the Reaction.

To what is the buff-and-pink colour-reaction due? Normal urine does not give the reaction, so that unless the reaction is inhibited by something else in the urine it is not due to a normal urinary constituent. It is not due to urea, since its intensity does not go hand in hand with the blood-urea; moreover, urea gives no colour with the diazo-reagent in acid or alkaline solution, in watery solution, or when mixed with serum. Nor is the reaction given by uric acid or creatinin. It is not due to any substance of the nature of a protein. It still occurs after boiling for a minute, after precipitating the protein with alcohol, or after boiling the alcoholic solution and filtering. After distilling off the alcohol from an alcoholic solution, the biuret test was negative. This diazo-reaction does not behave in the same way as that given by urochromogen or antoxyproteic acid. I was unable to exclude an amino-acid as the cause of the reaction. It must be mentioned that on two occasions where the serum gave a positive reaction, none was obtained in the cerebro-spinal fluid. In one case, however, giving a very deep colour in the serum, a faint buff (and pink on alkalinising) was obtained with the cerebro-spinal fluid, which was practically uncontaminated with blood.

I also examined the sera of three rabbits kindly given me by Dr. C. C. Twort. One of these had a growth in its pharynx, had taken no fluid for a day or two before its death, and died with a blood-urea of 300 mg. per 100 c.cm. Two others were suffering from nephritis and died with blood-ureas of 300 and over 100 respectively. All three of these sera gave a yellowish-buff colour (not given by normal rabbit sera), but no pink on adding alkali.

Summary.

The serum of patients with a severe grade of uræmia contains a substance which gives a characteristic colour-reaction with Ehrlich's diazo-reagent. The nature of the substance is at present undetermined. The observations of other workers that the serum-bilirubin is below normal in nephritis are confirmed.

EXCISION OF THE RECTUM.

ABDOMINO-VAGINAL AS AN ALTERNATIVE TO ABDOMINO-PERINEAL EXCISION.

BY VICTOR BONNEY, M.S., M.D., B.Sc. LOND., F.R.C.S. ENG.,

ASSISTANT OBSTETRIC AND GYNÆCOLOGICAL SURGEON, MIDDLESEX HOSPITAL; SURGEON TO CHELSEA HOSPITAL FOR WOMEN, ETC.

I COMMEND the operation I am going to describe to the consideration of those who practise abdomino-perineal excision of the rectum as an alternative to the latter operation under certain circumstances.

In the early part of last year a female patient was sent to me on account of a mass behind the uterus. When the abdomen was opened the mass proved to be a carcinoma of the rectum, about an inch above the bottom of Douglas's pouch. I closed the middle-line wound, performed colostomy as high up the pelvic colon as was feasible, and proceeded to consider the best way of dealing with such growth in a feeble woman between 60 and 70 years of age. I decided that she would probably not stand a classical abdomino-perineal resection, and I therefore performed the following operation.

I first packed the vagina with gauze soaked in violet-green as though for a Wertheim's operation, and then, reopening the middle-line incision, crushed and divided the bowel below the colostomy and separated it down to the upper surface of the levators, following thus far the technique of my friend and generous teacher, Mr. Ernest Miles. The uterus being pulled upwards and forwards, I then, with a scapel, divided the whole length of the posterior vaginal wall by cutting on to the gauze packing. The gauze packing was then pulled out via the vagina by an assistant. I had previously tied a strong piece of sterilised string around the upper end of the detached segment of bowel and this was passed on a forceps through the incision into the vagina where it was seized by the assistant, who, pulling upon it, pulled the whole length of freed bowel out through the vulva.

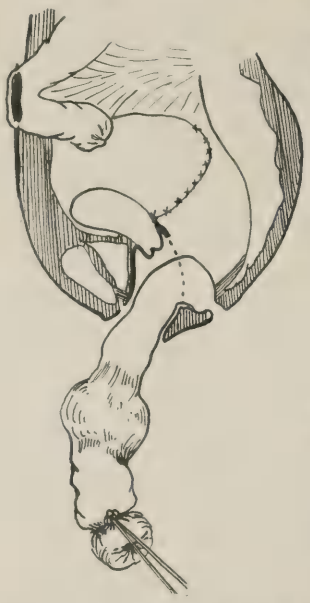

Diagram showing the bowel pulled through the incision in the posterior vaginal wall. The line of this incision is dotted. The position of the peritoneal roof is marked by crosses. The position of the growth in the bowel is indicated, as is the colostomy.

I then made a peritoneal floor exactly as though I was performing abdomino-perineal excision, except that it was far more easily and neatly done, as there was no mass of bowel to sew over, but, instead, a deep empty hole between the back of the vagina and the face of the sacrum. The abdominal wound was then closed (see diagram).

The patient was now placed in the lithotomy position with the freed bowel hanging out of the vagina, and I found there was length enough of bowel below the growth to enable me to crush and divide the bowel about two inches from the anus. I proceeded to do this and then inverted the ligatured end by a purse-string. Finally, the hole in the posterior vaginal wall was closed by a continuous catgut suture, a small gap being left at its lower end, through which a tube was passed into the empty space behind the vagina. The operation was relatively easy and rapid, and except for a little bleeding from the vaginal wall there was no hæmorrhage to speak of and no shock, and she recovered well.

I am not aware of this method having been described before, and my object in recording it is to suggest it as an alternative to the classical operation. The superior ease with which the gap left by the removal of the bowel from the hollow of the sacrum can be roofed over by peritoneum is very marked, especially by contrast with these cases of abdomino-perineal excision, where the detached bowel is hypertrophied and full of flatus. The avoidance of the perineal incision and the cutting of the levators, which is the stage where most of the shock and bleeding is incurred in the abdomino-perineal operation, is also a great gain, and where the growth is above the level of Douglas's pouch (and it is for such cases that the operation is specially suitable) the non-removal of the last inch or two of the bowel will not materially affect the patient's chances of cure.

If it be desired to remove this last two inches, the middle-line incision in the posterior vaginal wall could be carried down to the vaginal orifice and continued round the anus from that point, thus minimising the extent of the perineal wound and avoiding the excision of the coccyx.

ANIMAL TUMOUR CELLS MADE RESISTANT TO X RAYS BY X RAYS.

BY S. RUSS, D.Sc., F.INST.P.

(*From the Cancer Research Laboratories, Middlesex Hospital.*)

PREVIOUS experiments [1] have shown that when animal tumour cells are given a dose of rays from radium just less than lethal they may remain in the body for some months without showing any sign of growth, but eventually they begin to grow steadily, although, as a rule, at a slower rate than the normal. The experiments described below show that if tumour cells are irradiated with almost a lethal dose, their descendants will not be so sensitive to the same dose if it is repeated some time afterwards, and eventually the tumour cells may become extraordinarily resistant to the rays.

Experimental Work.

In the X ray treatment of cancer this fact is obviously of importance, and I am recording briefly a series of experiments which has so far lasted about a year. Previous experiments have shown that, in order to give a lethal dose of X rays under certain specified conditions of distance and output of radiation, the exposure takes about 56 minutes for the tumour used in these experiments—viz., Jensen's rat sarcoma. The chronological sequence of the experiment is given below. All the experiments in which radium was used were carried out in vivo, the X ray experiments were all done in vitro.

Expt. 1.—An inoculation of a normal rat sarcoma grew to size $4{\cdot}5 \times 4{\cdot}9$ cm. in seven weeks. A platinum tube containing 50 mg. of radium bromide was inserted into the middle of the tumour, fixed by sutures and left in position for 24 hours. Portions of tumour 2 cm. from the mid-point of tube were then removed and inoculated into ten rats. Eight tumours grew at very nearly the normal rate of growth.

Expt. 2.—One of these tumours (Expt. 1) grew to size $2{\cdot}2 \times 2$ cm. in three weeks, and a 10 mg. tube of radium bromide was inserted into the tumour and left for three days. Portions of tumour 0·7 cm. from the mid-point of the tube were removed and inoculated into seven rats. One tumour grew at about one-twentieth of the normal rate of growth.

Expt. 3.—The tumour last mentioned grew to size $1 \times 0{\cdot}8$ cm. in two months; it was transplanted into six normal rats. Five tumours grew at about one-third of the normal rate of growth.

[1] Dr. Helen Chambers and S. Russ: Proc. Roy. Soc., 1913, B, vol. lxxxvi.

Expt. 4.—One of these slowly growing tumours (Expt. 3), which grew to size 2·3 × 1·7 cm. in ten weeks, was excised and thin slices exposed to X rays for 45′ and 60′. The piece irradiated for 45′ was inoculated into 20 rats and 17 (i.e., 85 per cent.) tumours grew at about one-seventh of the normal rate. The piece irradiated for 60′ was inoculated into 24 rats and 15 tumours (i.e., 62 per cent.) grew at about one-twelfth of the normal rate.

Expt. 5.—One of the tumours in the 60′ batch (Expt. 4), which grew to size 1·2 × 1·1 cm. in five weeks, was excised and thin slices exposed to X rays for 90′ and 135′. The piece irradiated for 90′ was inoculated into 20 rats and ten tumours (i.e., 50 per cent.) grew at about one-sixteenth of the normal rate. The piece irradiated for 135′ was inoculated into 17 rats, no tumours formed, but in five animals small nodules persisted for about three weeks.

Expt. 6.—One of the tumours in the 90′ batch (Expt. 5), which grew to size 1·5 × 1·4 cm. in four weeks, was excised and thin slices exposed to X rays for 90′, 135′, and 180′. The piece irradiated for 90′ was inoculated into 19 rats and eight tumours (i.e., 42 per cent.) grew at about one-twentieth of the normal rate. The piece irradiated for 135′ was inoculated into 18 rats and two tumours (i.e., 11 per cent.) grew very slowly. The piece irradiated for 180′ was inoculated into 14 rats and three very small tumours grew which measured about 5 × 5 mm. at the end of one month.

Expt. 7.—One of the tumours in the 135′ batch (Expt. 6), which grew to size 1·3 × 1·1 cm. in five weeks, was excised and thin slices exposed to X rays for 140′ and 200′. The piece irradiated for 140′ was inoculated into 15 rats and two small nodules have persisted for six weeks. The piece irradiated for 200′ was inoculated into 15 rats and two small nodules have persisted for six weeks.

It will be seen that at Expt. 5 in the experimental series the tumour cells had developed an increased resistance to X rays, so that an exposure of 90 minutes was not enough to prevent a considerable proportion of tumours growing. In Expt. 6 tumour cells had grown when transplanted into rats, though they had had an exposure lasting 135 minutes. In other words, the lethal dose has been increased about two and a half times.

Ten years ago Nogier and Regaud [1] drew attention to the clinical fact that malignant growths, when exposed to X rays, suffered a gradual diminution in their sensitiveness to the rays. They advanced the argument that the various fluids of the body played some protective part in this process. Marie, Clunet, and Raulot-Lapointe [2] exposed a sarcoma of the mouse repeatedly to X rays and showed that cells took on certain new histological features, which continued for some time after the X ray exposures were stopped.

From the method of experiment which has been used in the series described here, it is evident that the acquired resistance must be attributed to some action of the X rays upon the cells of the tumour or its stroma. There is a distinction to be noted between the clinical conditions of Nogier and Regaud's observations and the experimental conditions here. In the former the tumour which received the first doses of X rays became resistant to the rays when applied later; no doubt many of the original tumour cells were present in this later stage. By the experimental method of transplanting a fragment of the tumour and waiting for a tumour of considerable size to grow before irradiating it, we are dealing, at each stage of the experiment, with cells many generations removed from those which have actually received the rays. In spite of this, the degree of acquired resistance is very considerable.

Microscopic Examination.

In order to see whether any histological changes were detectable in the tumour cells which had acquired this slowness of growth and increased resistance to X rays, they were examined microscopically. Sections of the normal rat sarcoma and of tumour which had grown after an exposure lasting 135′ (Expt. 6) were mounted on the same slide and kindly examined for me by Dr. E. B. Krumbhaar, who knew nothing about the identity of the specimens. He reported no appreciable differences between the two sections. When the irradiation period was extended to 180′, Expt. 6 shows that very small tumours persisted for some time, but did not continue to grow; one of these was excised and sections mounted on the same slide as those of the normal sarcoma. Dr. Krumbhaar's report reads as follows:—

"A section about 4 mm. in diameter (irradiated sarcoma): There is a general concentric arrangement of tumour tissue, which is well circumscribed and surrounded by fat and fibrous tissue. Within the nodule are many large bodies of various kinds; either giant cells (with a single eccentric nucleus) healthy or in various stages of degeneration or quite structureless bodies (apparently degenerated giant cells). Empty spaces apparently denote where these bodies have dropped out or in some places are dilated lymph spaces or fat. The body of the nodule consists chiefly of spindle cells and coarse collagen, somewhat separated by edema fluid. The spindle cells are mostly sarcomatous with relatively few fibroblasts. Blood-vessels are not numerous and not altered. There is no cellular infiltration.

Larger section (untreated sarcoma): The tumour tissue, which is found immediately beneath the epithelium, is circumscribed, but surrounded by much more delicate fibrous tissue. The section is much more cellular, the cells stain much more sharply, and there is less collagen. No giant cells are seen, though there is considerable variations in the size of the sarcoma cells. The predominant cell is a short, fat spindle, with a large oval nucleus and finely divided chromatin. Another section shows tumour cells closely packed, with a very little collagen distinguishable."

Conclusion.

It looks, therefore, as if we can recognise by this method of irradiation a number of steps in the action which X rays have upon these tumour cells, beginning after moderate doses with a slowing up of its normal rate of growth; with greater doses the tumour acquires an increased resistance to the X rays. When doses very near to the lethal dose are given, degenerative features appear in the cells which can be recognised microscopically. Experiments are in progress to see whether other animal tissues are similarly influenced by X rays.

The radium employed in these experiments has been lent to the Middlesex Hospital by the Medical Research Council.

THE METABOLISM OF COD-LIVER OIL BY DIABETICS.*

BY V. H. MOTTRAM, M.A.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF LONDON.

(*From the Household and Social Science Department, King's College for Women.*)

THE problem of feeding diabetics, though undoubtedly alleviated by the discovery of insulin, is still difficult. To obtain for them a diet of even passable calorie value without the disadvantages of a glycosuria or an aceto-aceturia, is an undertaking. If we could find a fat which is metabolised along other routes than that of the keto-acids and does not, in avoiding that path, give rise to carbohydrate-like bodies, then it would be of immense value. The possibility of the unsaturated fats emerges. Leathes [1] has suggested that the undoubted manufacture of unsaturated fats by the animal body, probably in the liver, is a step in their metabolism to enable them to be more readily oxidised later. He compares it with the drying of gunpowder.

The easiest to obtain is, of course, cod-liver oil. This oil already has advantages over butter in having a higher calorie value, weight for weight, and a greater vitamin-A content. There is evidence that some di-basic organic acids [2] do not give rise to aceto-aceturia in diabetics, and also that some unsaturated fatty

* The expenses incurred in this work were defrayed by a grant from the Medical Research Council, to whom my best thanks are due.

[1] THE LANCET, 1909, i., 583.

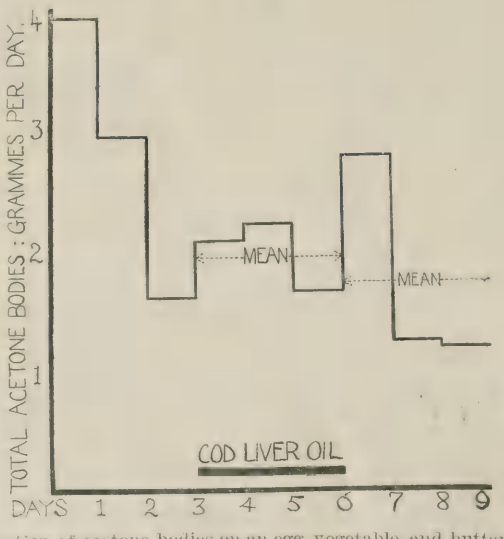
[2] Baer and Blum: Arch. f. Exper. Path. u. Phar., 1906, lv., 89; 1907, lvi., 92; 1911, lxv., 1.

acids[3] behave similarly. There is a possibility that the fatty acids of cod-liver oil would, on metabolism, yield di-basic organic acids. On the other hand, the first stage in the oxidation of the unsaturated acid appears to be the formation of the saturated fatty acid.[4] Consequently, in view of the value of fish oils and fatty fish in dietetics, experiments were put in train to discover the path of metabolism followed by unsaturated fatty compounds in the diabetic organism.

With the kind permission of Prof. F. R. Fraser, and the coöperation and advice of Dr. George Graham, I was allowed to substitute cod-liver oil for butter in the diet of diabetics in the Sandhurst Ward of St. Bartholomew's Hospital, when they were at the stage of receiving an egg and vegetable diet with 25 or 50 g. of butter. Either the acetone and the aceto-acetic acid were measured iodometrically, or the total acetone bodies were estimated by v. Slyke's method. The latter method was preferred, for the former, while often giving beautifully concordant results, would, in spite of all precautions, with urine which had been preserved for a while, give most anomalous results. Nothing short of a 1 per cent. agreement in parallel estimations has been accepted.

The result is briefly this, that when the butter of the diet—25 or 50 g. respectively—was replaced by 1 or 2 oz. of cod-liver oil in the form of a 50 per cent. emulsion, there is no evidence that the fat of the cod-liver oil is metabolised along other lines than those of butter. Unsaturated fats follow the same path as saturated fats. Consequently, the unsaturated fats in herring, sprats, salmon, or sardines, in the feeding of diabetics, must stand on their merits of high calorie value and vitamin-A content, rather than any antiketogenesis of their metabolism.

The accompanying curve perhaps best demonstrates this. The patient was on a diet of egg, vegetables, and



Excretion of acetone bodies on an egg, vegetable, and butter diet when the butter was temporarily replaced by cod-liver oil.

50 g. of butter per day, and making good progress. The total acetone bodies for three preliminary days were estimated, then for three days when the butter was replaced with a rather more than an equivalent amount of cod-liver oil, and finally, for three more days on the original diet. As will be seen, there was a slight rise on the first two days of cod-liver oil, followed by a fall to the original amount. The first day after the removal of it from the diet there is a rise, followed by a fall to a still lower point. Should anyone wish to argue from this curve that the removal of the cod-liver oil from the diet removes an anti-ketogenic substance from the diet, other curves could be adduced in which the opposite occurred. A more reasonable explanation is that the amount of ketosis in this patient was diminishing owing to his steady increase of power in metabolising carbohydrate, and that the ups and downs are variations due to chance. The mean excretion of acetone bodies during the cod-liver oil period was 1·93 g. per day, and in the succeeding three days 1·72 g. There is no evidence here or in other experiments that the metabolism of cod-liver oil pursued a different path from that of butter.

Clinical and Laboratory Notes.

UNUSUAL VARIETIES OF CALABAR SWELLINGS,

WITH A NOTE UPON THE ÆTIOLOGY OF THE CONDITION.

BY GEORGE C. LOW, M.D. EDIN., M.R.C.P. LOND.,
SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES; LECTURER, LONDON SCHOOL OF TROPICAL MEDICINE.

IN 1911, in a paper entitled Filaria Loa,[1] I described a rare form of Calabar swelling involving the hand and the whole of the forearm. Since that date, till the other day, I have not encountered such a case again, though Dr. P. Manson-Bahr tells me that he saw one a little time ago. Calabar swellings, as is well known, are connected in some way with *Filaria loa* infections and take the form of painless, non-inflammatory, white, waxy-looking, œdematous, solid swellings, usually about the size of a pigeon's or goose's egg. They last from two or three days to a week and gradually disappear of their own accord. They may occur on any part of the body. In the rare diffuse form to be described the swelling implicates the whole hand and forearm, the characteristic features of the localised swelling being present, however—viz., the peculiar white waxy-looking appearance, absence of redness, the solid nature of the œdema, not definitely pitting on pressure, painless—apart from the distension of the part—apparently causeless in origin and disappearing again of its own accord.

The following is the history of the case in question:

Patient born in England. Went abroad first in 1900 to Sierra Leone, South Africa 1904–1906, Nigeria 1911–1916, Cameroons 1914–1915, German East Africa 1916–1918, Northern Nigeria 1918–1923.

Previous Illnesses.—Malaria, dysentery (German East Africa).

Present Illness.—Swelling of right hand, slight, February, 1923. Again April, 1923, then clear till Dec. 16th, 1923, when right hand and whole of right forearm swelled up. Board-like swelling, no redness, no inflammation.

Condition on Examination.—I saw the condition on Dec. 28th, 1923. Very typical of the usual Calabar swellings—white, no redness, consistence pretty solid, difficult to pit on pressure. Extends up from hand, all of which is swollen, to elbow. No pain; just the discomfort of the tense feeling. Patient unable to move fingers properly.

On Dec. 31st I saw the patient again; swelling going down slowly. A slight papular condition present. Papules white, not red. No itching or special discomfort.

Blood Count.—Leucocytes 9000. Differential count: Polymorphonuclears 35, large mononuclears 4, lymphocytes 24, eosinophils 37 = 100.

On Jan. 7th, 1924, the swelling was slowly going down. On the 14th it was practically gone.

The photograph illustrates the condition. A point of interest is the time the condition lasted—viz., about a month. Small swellings are usually gone in a week or ten days.

Another rare form I wish to describe is that where the penis is attacked. I recently saw a good example of this in a patient who had already suffered from several Calabar swellings in different parts of his body. Long experience of such swellings enabled me to say at once what it was and to prognosticate that it would disappear in a few days of its own accord.

[1] Journal of Trop. Med. and Hyg., Jan. 2nd, 1911.

which it did. Another case showed the whole of the hand considerably swollen, especially in the dorsum, with no implication of the forearm.

Etiology of the Condition.

In the *Journal of Helminthology* (1923, i., 191) I described the result of puncturing such a swelling, and looking for filarial embryos, on Sir Patrick Manson's assumption that the swelling might be due to a female worm giving birth to young ones. I definitely proved that this was not the case, and then threw out a suggestion that the cause might be due to the death of a worm with an escape of toxin or from some poisonous product of decomposition.

I have now collected some very strong presumptive evidence that such is the case. In the patient just

Calabar swelling implicating whole of right hand and forearm.

mentioned, who suffered from a Calabar swelling of the penis, I noticed as the swelling went down a small nodule which felt exactly like a coiled-up worm. I consulted at once with a surgeon upon the advisability of cutting down and removing this, but he was afraid of hæmorrhage from the corpus cavernosum, on the surface of which the mass apparently lay, while the patient—probably rightly so—refused absolutely to have any surgical interference. I had to content myself then with daily manual examinations. The little mass grew less and less and finally disappeared a considerable time after the general swelling had subsided. I believe then, that in this instance a worm had died: and in doing so had set free some toxic substance, which caused the œdema and so produced the Calabar swelling. Occurring as it did in the soft tissues of the penis, one was able to detect the little coiled-up mass, of what I took to be the worm, and which one would almost certainly have missed if it had been in the ordinary solid connective tissues. It is highly probable, then, that this is the explanation of the ætiology of the peculiar solid œdematous swellings known as Calabar swellings.

There is really nothing against the idea, nor does the fact that the patient may have many Calabar swellings militate against it, because we know from autopsies that infections with 20, 30 or more adult worms are not uncommon. *Filaria bancrofti* in dying, we know, often give rise to inflammation and even to septic troubles eventuating in abscess formation. *Filaria loa*, on the other hand, apparently give rise to localised œdematous swellings of an angio-neurotic nature.

A NOTE ON VERTIGO.

By RICHARD LAKE, F.R.C.S. ENG.,
G. E. DUVEEN LECTURER IN OTOLOGY, LONDON UNIVERSITY.

IN cases of vertigo the examiner has such a wide field of origin to choose from that any factor which appears frequently in such cases becomes at least of academic interest: and after this factor has been submitted to scrutiny by competent authority its place is established according to its value. In a paper which I read before the Academy of Medicine in New York,[1] I made a list of causes of aural vertigo; the past decade has modified my views considerably, but I quote the grouping as I then presented it.

Aural Vertigo.

Section I.—Peripheral causes: (*a*) Chronic progressive middle-ear deafness; (*b*) hæmorrhage into labyrinth and embolism: (*c*) traumatism.

Section II.—Aural vertigo due to altered state of blood pressure: (*a*) increased blood pressure: and (*b*) diminished blood pressure.

Section III.—Aural vertigo due to general systemic causes: (*a*) leukæmia: (*b*) occasional: (*c*) with ocular symptoms; (*d*) specific; (*e*) cerebral anæmia.

This classification fails, especially when one is dealing with extra-aural cases, the more important of which were considered by Dr. Gordon Holmes in the discussion on Vertigo at the Royal Society of Medicine on Feb. 26th last.[2] The most important clinical feature of the majority of cases which I have seen in private and hospital practice, however, is that in Section II.(*b*), since 1912 I have made a point of ascertaining the blood pressure of these patients. The result certainly astonished me; a low blood pressure was so common. The frequency with which I found that something was apparently acting as a depressant upon the heart's action was also unexpected. I would go so far as to say that a, if not the, principal agent—i.e., in-patients with a normally low blood pressure and over 15 years of age—was tobacco.

The action of a low blood pressure upon the function of equilibrium is central and may be severe, embolic; transitory, or anæmic in its effect. In the severe form the vertigo is accompanied by deafness, which may be capable of improvement. In the less severe or transitory form I usually find that removal of the exciting cause and administration of remedies calculated to restore the blood pressure to normal is sufficient to prevent recurrence of the symptoms. A very interesting example of the effect of the blood pressure in producing vertigo is the following: A lady, aged 69, consulted me for vertigo, stating that she had been under a heart specialist for very high blood pressure, which he had reduced to 140. The vertiginous attacks were coincident with this reduction. Allowing the blood pressure to increase somewhat put an end to the attacks.

I have no record of high blood pressure as a cause of vertigo, although it is quite commonly present in cases of tinnitus in the middle-aged. Amongst other cases I have seen, syphilis has been fairly frequently present.

[2] THE LANCET, March 1st, p. 445.

LIVERPOOL NEW MATERNITY HOSPITAL.—Princess Mary Viscountess Lascelles visited Liverpool on March 12th to lay the foundation-stone of the new Maternity Hospital. The site for this hospital has been presented to the city by the late Sir William Hartley, together with a sum of £25,000, to which a further sum of £27,000 has been added by voluntary subscriptions. The site is conveniently placed near all the academic buildings of the city, and the erection of the new building is to be begun at once. The hospital aims at being a complete modern building to accommodate 90 patients, with facilities for increasing the number of wards as funds permit. Amongst those presented to Princess Mary, before the luncheon at the Town Hall given by the Lord Mayor and the City Councillors, were three members of the honorary medical staff, Dr. J. E. Gemmell, Dr. J. H. Willett, and Miss Frances Ivens. In the afternoon a visit was paid to the present maternity hospital on Brownlow Hill.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

POSSIBLE SUBSTITUTES FOR COCAINE.

A GENERAL meeting of the Society was held on March 12th under the presidency of Sir WILLIAM HALE-WHITE, when a debate was held on this subject.

Dr. H. H. DALE, in introducing the discussion, said it might seem strange that the question of replacing cocaine by artificial substitutes had not arisen in relation to other alkaloids which also were dangerous drugs of addiction, but in some respects the case of cocaine was unique. The effects of cocaine after absorption complicated its use in medicine and surgery by producing undesirable symptoms. Theoretically it was not impossible that a substance might be found having the valuable properties of cocaine without its harmful ones. He proceeded to consider the various substances which had been put forward as substitutes for cocaine, with the idea of discovering how far any or all of them together could fulfil its functions and avert its dangers. He enumerated the list of properties of cocaine.

1. It had a powerful and long persisting local anæsthetic action, with penetrative capacity in the tissues, so that it could produce anæsthesia of relatively deep structures.

2. When locally applied to a mucous membrane it caused constriction of the small blood-vessels, producing ischæmia and deturgescence. It also had a mydriatic action.

3. It showed but little tendency to irritate or devitalise the tissues in the area it was injected into.

Its undesirable properties were :—

4. It was somewhat unstable ; solutions of cocaine could not be sterilised by boiling without danger of hydrolysing it into benzoic acid and methylecognine, when its local anæsthetic action became destroyed.

5. It was dangerously toxic when absorbed into the general circulation, and this limited its use for producing anæsthesia by injection. And, unless only small quantities of dilute solutions were used, its application to intact mucous membranes was not without danger. There ensued a primary stimulation of the brain, with acceleration of cerebral processes, loss of sensation of fatigue, and a feeling of well-being and euphoria. Following this were restlessness and garrulity, accelerated respiration and heart-beat, a rise of arterial blood pressure, and a heightened temperature. A further stage was depression, collapse of blood pressure, slow and feeble heart-beat, loss of consciousness, and if death ensued it was from paralysis of the respiratory centre.

6. The primary stimulant effect of a dose which was not immediately dangerous was apt to leave a desire, in a person of weak control, for a repetition.

Of the substitutes which had been put forward to replace cocaine, he spoke only of those which had had some measure of success, omitting also such substances as orthoform and anæsthesin, which were suitable only as analgesic dusting powders. Of the eucaines, only β-eucaine had had practical success. He also dealt with tropacocaine, stovaine, alypine, novocaine, and butyn. In intensity and persistence of local anæsthetic action, cocaine seemed to stand unrivalled, excepting only butyn. Novocaine was much more rapidly destroyed in contact with the tissues, so that it did not penetrate deeply. Tropacocaine some regarded as equally active with cocaine in local application, but it was more evanescent. He hoped to hear more of the anæsthetic efficiency of butyn.

For none of the suggested substitutes was it claimed that they resembled cocaine in constricting the blood-vessels and producing shrinkage of mucous membrane. Had any of the available substitutes a like action, or could it be produced by locally mixing the anæsthetic with a suitable proportion of adrenalin ? And was the mydriatic action of cocaine considered important by ophthalmologists ? All the suggested substitutes seemed to be more stable than cocaine to boiling in watery solution, and most of them possessed less general toxicity than cocaine, though to this alypine seemed to be an exception. Eucaine, tropacocaine, stovaine, and novocaine were much less liable than cocaine to produce bad symptoms if absorbed into the general circulation. Butyn seemed to be even more toxic than cocaine judging by animal experiments ; yet in human therapeutics there had been an absence of bad symptoms from accidental absorption. The substitutes which had sufficient potency and penetration had the drawback of irritating and devitalising the tissues, while novocaine—ideal in this—was deficient in power and persistence. By choosing for each separate purpose the appropriate substance cocaine had been largely replaced by safer substitutes. For infiltration-anæsthesia and for nerve-blocking most needs were filled by novocaine. For causing analgesia by intrathecal injection, stovaine and tropacocaine had been largely used. When speaking of less dangerous substitutes he explained that he had in mind not only danger of immediate toxicity, but the more subtle danger of addiction. The problem created by the cocaine habit had led the Ministry of Health to appoint a special committee (of which he was a member) to discuss the question, and the terms of reference were, "To investigate the comparative value for therapeutic purposes for which cocaine is at present used, of various possible substitutes, and the evidence as to risk, if any, of such substitutes becoming drugs of addiction." He had failed to elicit evidence of a case of addiction to any local anæsthetic other than cocaine. Still, he would be interested to learn whether any of the substitutes had been found to produce a mental exaltation and euphoria comparable to that produced by cocaine, and providing the basis for its habit-forming property. A further important question was that of the extent to which the proper use of cocaine in medicine and surgery involved the danger of producing the drug-habit. This included the question of what was the proper use of cocaine. He thought cases in which the use of cocaine by the patient, on a prescription, for application had resulted in the formation of a vicious habit were rare. He expressed himself as very interested to know whether a single application of cocaine by the medical man himself had ever been known to result in the patient acquiring the habit. If not, the further question arose whether cocaine itself was indispensable for any other purposes, or whether those other uses could be met by one or other of the substitutes. Would medical practice in any direction be materially hampered if the use of cocaine were limited to direct application by the medical man himself, with prohibition of dispensing or prescription for the patient ?

In conclusion, he said that, under the title of the discussion, the only practical question was whether any of the possible substitutes, or all of them together, so far fufilled the functions of cocaine that medicine and surgery could do without the latter. No negative answer to this question could at the present time be final. Synthesis of the drug had already resulted in a series of isomeric cocaines being produced. A wide synthetic field still remained to be explored, and there was always the possibility that from the research would emerge the ideal local anæsthetic, potent, penetrating, astringent, and free from immediate toxicity or habit-formation. If no efficient substitutes were yet available the question needing an answer was, could the use of cocaine in the profession be so restricted as to minimise its dangers without real detriment to practice ?

A Resolution Withdrawn.

The PRESIDENT mentioned that Dr. Dale had suggested that the meeting might like to pass a resolution on the matter, and if so, it would be wise to bring it before a fairly full meeting, as many might have left if it were deferred until later. The suggested wording was : "This meeting, while regarding the retention of cocaine as essential to medical and surgical practice, is of opinion that its use might with advantage be restricted to the application by the physician or surgeon himself, and the prescription or dispensing of it might be abandoned."

Prof. W. E. DIXON proposed this, in order to open the discussion.—Mr. H. J. BANKS-DAVIS seconded.

Mr. N. BISHOP HARMAN moved to add "except when prescribed in such vehicle, or with such other

drug, as to prevent its use for purposes other than that intended."—Mr. MARK HOVELL seconded this.

Mr. HARMAN, in support of his addition, said it was possible to prescribe cocaine in castor oil.—Mr. ERIC WATSON-WILLIAMS said he thought it was a startling thing that any action should be taken to limit the discretion of a physician or surgeon in prescribing anything he thought fit for use.—Dr. W. HILL deprecated passing anything like a panic resolution.—Dr. DALE interposed that it would be better to withdraw the resolution than to put it to the vote and have it rejected.

The proposal was then withdrawn by the PRESIDENT on the ground of due notice not having been given.

Discussion.

Prof. W. E. DIXON said it was remarkable that up to the present time no alkaloid had been produced synthetically superior to those provided by nature. But there was more hope with cocaine, because its action was essentially one on the central nervous system, the local anæsthetic effect being, in a sense, an accident. Montigazza spoke of the effect of chewing coca leaves as that of producing unspeakable beatitude. On two occasions the speaker had had 1½ gr. of cocaine injected into himself; and the only effects were some tremulousness and excitement, slight frontal headache, and wakefulness, and no desire to repeat the experiment. The effect did not differ materially from that following the injection of 4 or 5 gr. of caffein. Mariani, who popularised cocaine in Europe, gave some to Pope Leo XIII., and His Holiness presented the giver with a gold medal to show his gratitude for a medicine which so assisted him in the practice of his asceticism. A local anæsthetic was a general protoplasmic poison. β-eucaine, tropacocaine, and stovaine were now generally regarded as not satisfactory, because in the doses necessary to produce anæsthesia they also caused some irritation of other tissues. Eucopenal toxin was 20 or 30 times as powerful as cocaine, but it was useless in medicine because in very minute doses it not only destroyed the nerve fibres, but injured other tissues; it had not sufficient selective action. Local anæsthetics acted by paralysing sensory nerve-endings; and in the case of a mixed nerve they paralysed the sensory fibrils before the motor. Heroin had been introduced 15 years before a case of addiction was described, despite the fact that it was an ideal drug of addiction. The bowels of the morphine addict worked about once a week, but the heroin addict was almost normally regular in that respect. He thought that before the war cases of cocaine addiction must have been very rare. The habit started around the lines in France, thence it spread to Paris, to London, and, much later to Berlin. Men engaged in the war were in a highly emotional state when they came away from the conflict, and the mental exaltation caused by the drug seemed to bring to them the relief they craved. Yet they did not want to repeat it for a number of days. Since the war, however, cocaine snuffing had become more general. Dr. Copeland had been working a good deal at butyn; this exerted a stimulant action on a portion of the brain cortex, and its effect was temporary. After a time there followed a mild degree of depression. Butyn also temporarily paralysed, in relatively small doses, the nerve ganglion cells throughout the body. The cells in the autonomic system remained paralysed for from five to ten minutes. One objection which had been made to butyn was that it promoted free secretion; if absorbed there was great salivation, and when put into the eye the lacrymal gland secreted freely. Sometimes butyn did not act, and the reason, he thought, was that it was precipitated by even very weak solutions of common salt. Added to egg-albumen it caused a white precipitate. In the nose strong solutions of butyn paralysed the sympathetic nerve-endings.

Prof. C. S. GIBSON uttered a strong plea for more chemical research on this subject, on the lines so successfully carried out by Mr. Fourneau, in Paris, who synthesised stovaine, alypine, and some others. But this work, to yield its full benefit, must result from the collaboration of the chemist with the physician and the pharmacologist. He could not see what special advantage there could be in butyn over novocaine. Butyn compounds were capable of existing in optically active form, but the compounds which had been tried clinically had been only in the inactive form. The ideal cocaine substitute must be an optically active compound. Another part of the investigation was the stereo-chemical examination of these compounds. Dr. King had recently been investigating the stereo-chemical properties of β-eucaine and iso-β-eucaine, and Dr. J. H. Burn had arrived at the conclusion that the anæsthetic action of those compounds, whether optically active or not, was approximately equal. But he (Prof. Gibson) did not think that invalidated the necessity for a more complete stereo-chemical investigation of all the possible substitutes for cocaine. The most successful line of research, however, would be the synthesis of a compound on a cocaine model. Synthesis of cocaine had been achieved, and there was no difficulty about repeating it. The naturally occurring cocaine was levo-rotatory; the product synthesised in the laboratory was optically inactive. Yet no one had succeeded in resolving the synthetic cocaine so as to try and see whether dextro-cocaine might not be a desirable cocaine substitute. The most useful line of research would be to start from the cocaine model and build up as many compounds as possible, then to start a stereo-chemical investigation in addition, getting the pharmacologist to evaluate these drugs, which could then be handed over to the clinician.

Mr. T. B. LAYTON said the drugs under discussion were of interest to him solely in the light of surgical technique. Local anæsthetics were a means of replacing general anæsthesia by something more efficient, more safe, and more pleasant. He believed the future of rhinology was intimately wrapped up with the subject of local anæsthesia. Thus the need of a good and safe local anæsthetic was very great. In the matter of producing shrinkage he believed that when adrenalin was added to the local anæsthetic the latter was not quite so valuable as without it. He thought the clinician should tell the laboratory worker what he wanted, and that new drugs were really needed, though whether they would efficiently replace the present ones was matter for discussion. There were many gaps in the series investigated and when those gaps had been filled the ideal drug might emerge, one which had the advantages of cocaine without its disadvantages. It was the minor degrees of toxicity with which the clinician was concerned. When dealing with a patient and giving him drugs he found it almost impossible to say which symptoms were due to the drug and which to the anxiety and apprehensions of the patient who was about to endure an operation on the nose.

Mr. F. N. DOUBLEDAY, speaking as an odontologist, referred to the British Dental Association's questionnaire to the dental surgeons of the country, which showed that three-fourths of those who replied thought cocaine was essential for dental work, while the remaining one-fourth, comprising men connected with various dental hospitals, thought cocaine was not necessary, as efficient substitutes for the purpose had been found. He believed medical men had not yet appreciated how valuable dental operations could be as affording a clinical test of the relative value of the various substitutes for cocaine which had been suggested. He hoped Dr. Dale, in his reply, would say whether the manner in which the sub-groups of atoms were brought into the molecules made any difference to the properties of the substance. He had recently tried various anæsthetics of the eucaine group, and he found many of them very irritating, though they did not cause much pain. If local anæsthetics came into contact with alkaline water, or lysol, many of them were precipitable, and their chemical character was thereby much altered. For dental purposes novocaine could be proved to be an efficient local anæsthetic.

MR. S. F. ST. J. STEADMAN agreed that novocaine was an efficient anæsthetic. One drawback in the substitutes was the occurrence of after-pain. That could be minimised by using fresh solutions. Butyn, which he had used in 200 cases, did not produce anæsthesia quicker than did ordinary novocaine, and in some cases the after-pain of butyn was very severe, sometimes lasting as long as three or four hours. By the use of freshly distilled water the after-pain from a local anæsthetic was less than after nitrous oxide gas.

MR. ERIC WATSON-WILLIAMS (Bristol) spoke of published cases of cocaine addiction before the war, and said that between 1888 and 1895 cocaine was used largely in the treatment of morphine addiction. Clinically, the real objection to cocaine was its toxicity. Figures of comparative toxicity had been published, based upon animal experimentation, but the limitation of the latter as a parallelism to human experience should always be remembered. Butyn, he considered, gave a perfect anæsthesia. All the substitute drugs were dangerous unless used with great care, hence the equipment of the clinician should be as simple as possible. The real objection to cocaine lay in the fact that it was poisonous, and in this respect the substitutes did not differ. There seemed to be a definite relationship between the toxicity and the anæsthetising power. Clearly, a local anæsthetic must be a substance with a special affinity for nervous tissue. If feasible, he thought experiments with these drugs on apes would yield the most dependable guide for man. He laid special emphasis on the question of the concentration of the drug in its relation to the toxicity. In cocaine, for example, in concentrations above 2 per cent., especially above 5 per cent., the toxicity was not very materially affected by variation in the concentration, but in larger dilutions the toxicity of the same gramme of cocaine fell rapidly. The importance of this lay in the fact that clinically only the dilute solutions were injected. By sufficient dilution a point was reached at which the drug was entirely non-toxic, and for cocaine this point was probably below the limit of clinical usefulness. In the case of novocaine, with adrenalin added, it was near ¼ per cent.—i.e., it was impossible to administer subcutaneously a dose of novocaine which would kill a guinea-pig. Perhaps it was along this line that a solution of the problem would be found.

MR. FRANK COLEMAN said he knew of no anæsthetic which was so efficient as cocaine for the removal of tooth pulps. The public spoke of local anæsthesia as if only one drug was used to produce it, cocaine, and after an operation patients frequently expressed surprise at the absence of pleasurable sensation following the injection. He believed cocaine could be sterilised if boiled in a vessel which did not contain alkali.

Reply.

DR. DALE, in reply, said it was shown some time ago that novocaine, in whatever concentration it was injected, seemed, by hypodermic injection, to be very much less toxic than cocaine, but if the injection were done directly into the blood-stream the contrast was much less striking. Novocaine was apparently either very rapidly eliminated through the kidneys, or was quickly hydrolysed into inert compounds when it got into the blood-stream. Butyn appeared to be a more stable substance. He spoke of a new local anæsthetic he was soon to have an opportunity of trying privately, in which he would seek the collaboration of some of his colleagues. He spoke hopefully of the prospects of a suitable substitute being eventually found.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this Association was held on March 11th, Miss CHADBURN, the President, being in the chair, when papers were read on

Anæsthesia and Anæsthetics.

DR. H. N. PAYNE, discussing general anæsthesia, said that she preferred ether to chloroform or chloroform mixtures, on grounds of easy administration and safety. Patients much preferred induction by gas, and this was the routine method used by her, followed by closed ether. For toothless patients in the Trendelenburg position, in the late stages of long operations, in abdominal cases where the patient was acutely ill, and in thyroid operation she preferred the open method. She gave chloroform only to patients who appeared unsuitable subjects for ether, on grounds of chest complications, age, or stoutness. It was not her practice to give scopolamine and morphine before an anæsthetic, and she gave atropine only in selected cases.

MRS. A. GILLIAT, speaking on anæsthetics for ear, nose, and throat operations, explained how the technique had to be adapted to meet special difficulties caused by liability to an obstructed air-way. Anæsthetics for ear operations were less difficult than for those on nose and throat. The use of open ether was not altogether satisfactory, and she preferred induction with chloroform or C.E. mixture. She gave details of the technique employed in her practice for mastoid and lateral sinus operations, for operations on the nose, and for guillotine and dissection and enucleation operations on the tonsils in children and in adults.

MRS. TINDAL-ROBERTSON discussed spinal anæsthesia. This method was useful in cases of operation at the level of the umbilicus or below, especially in asthmatic or bronchitic cases, or for those with certain heart diseases. For prostatectomic operations on stricture of the urethra and for amputations in cases of diabetic gangrene it was the method of choice. Cases of Wertheim's operation and excisions of rectum did better under spinal anæsthesia combined with twilight sleep or general anæsthesia. The injection of stovaine was liable to cause a fall of blood pressure which might be dangerous when the patient was badly shocked before the operation. Where the patient was not shocked to begin with, spinal anæsthesia diminished shock. In spinal anæsthesia given by modern methods it was considered essential that the patient should not be allowed to get frightened. A patient who had had injections of hyoscine, morphine, and atropine before being brought into the theatre was already drowsy or almost asleep, though she could be aroused, and if all unnecessary noise were excluded she remained asleep. If the operation were delayed or the patient difficult, very slight chloroform inhalations would be sufficient to put her to sleep. Mrs. Tindal-Robertson dealt with the technique of injections, and then with certain complications which might arise.

DR. ENID MOORE described the technique of gas and oxygen anæsthesia, laying stress on the need for slow induction. For the alcoholic patient, introduction of ether vapour into the mixture was desirable. At the Infants Hospital, Vincent-square, gas and oxygen was used exclusively for abdominal operations, and the statistics appeared to show fewer fatalities than did other methods; especially in cases of congenital pyloric stenosis was it of value. Since an infant was liable suddenly to become deeply anæsthetised without preliminary warning, it was wise to give a proportion of 1 oxygen to 2 nitrous oxide instead of 1 to 4, as in adults. Occasionally the introduction of small quantities of ether vapour appeared to be stimulating. For adults, gas and oxygen was useful in stomach operations, thyroid operations, head operations, Cæsarean sections, in bronchitic patients and heart cases other than those with myocardial degeneration. Finally, Dr. Moore pointed out that vomiting might occur during operation when anæsthesia was too light or too deep and the narrow intermediate limits had to be observed.

MRS. MARGARET BRADY, speaking of ethyl chloride anæsthesia, said that she used the Loosley apparatus for closed administration, which she demonstrated.

Administration was not difficult, and proved a useful half-way house between nitrous oxide and chloroform. The advantage for dental anæsthesia in children was that the child had to come up once only, instead of several times, for a multiple extraction. Caution was needed, since ethyl chloride was a quick anæsthetic. Change in respiration was, in the speaker's experience, far the most useful of the signs to watch. Another danger sign was change of colour, especially to a waxy pale colour. The drug had a cumulative effect, and it was not wise to push its administration till the pupil was fixed, central, and dilated. The lessening rigidity of the jaw muscles was a useful practical sign of increasing depth. The only fatalities known to Mrs. Brady were caused by administration of a second dose, at the request of the surgeon, during the same operation and she strongly advised that this should never be attempted.

Miss L. ALDRICH-BLAKE spoke of anæsthetics from the point of view of the surgeon and of the patient. From the patient's point of view, the two most important things were that an anæsthetic should be (1) safe, (2) as little unpleasant as possible. Nearly all patients disliked the smell of ether, and therefore induction by gas or some other method was an advantage, both to the patient and the surgeon. In the future, probably a combination of local anæsthesia and some less toxic form of general anæsthetic than was in routine use at present, would be the rule. She had found the injection of 2 per cent. novocaine into the muscles and planes of the abdominal wall, and into extra-peritoneal tissue in the rectum, very useful in diminishing shock. From the surgeon's standpoint, where good relaxation was required, to obtain and maintain the free airway was the first essential. Miss Aldrich-Blake quoted statistics from the records of consecutive patients operated on by her at the Elizabeth Garrett Anderson Hospital to show that no appreciable risk from pulmonary complications after ether anæsthesia need be feared. Of 700 patients, only 12 had developed pulmonary complications which might possibly be attributable to the anæsthetic, none of them being fatal.

Dr. MINA DOBBIE spoke of the use of twilight sleep in general practice. She said that the advisability of twilight sleep during labour was still a matter of controversy, that many of the arguments used against it were the same arguments that were formerly employed against the use of chloroform. The method of producing it, the dosage, and the purity of the drugs, varied so much when twilight sleep first came into use that the arguments used then were at least out of date. Most of the conditions mentioned by Dr. J. S. Fairbairn in 1917 as special indication for its use had been given by early observers as contra-indications. For women nervous of pain this was an ideal method and was safe so long as it was remembered that amnesia and not analgesia should be aimed at. Dr. Dobbie traced the history of twilight sleep, and gave details of the technique of the three schools: (1) the single dose school, (2) the standard dose school, and (3) the individual dose school.

Mrs. E. HANDLEY-READ, speaking of anæsthetics for dental surgery, discussed the patient's common preference for an anæsthetic which would enable several teeth to be pulled out at the same time when necessary. This, when insisted on, entailed a general anæsthetic other than gas and oxygen. The disadvantages were the difficulty of obtaining a suitable firm reclining couch even in a nursing home, where such an operation should be done; the danger that a portion of tooth or debris might pass down the throat, the shock following multiple extractions, and the danger of leaving too many open sockets in a septic mouth. For gas a skilled administrator was desirable, the inexperienced were apt to take off the face-piece too soon. She did not trust closed ethyl chloride for children, but it was useful as an open method to produce unconsciousness and followed by gas. Mrs. Handley-Read discussed the merits of local and regional anæsthesia, both of which methods were now being increasingly employed by dental surgeons.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society on March 5th, Sir DAVID WALLACE, the President, in the chair, Mr. G. EWART MARTIN read a paper on the

Application of the Bronchoscope in the Diagnosis and Treatment of Certain Affections of the Chest.

He pointed out the apparent rarity of cases of foreign bodies in the bronchi in this country, as compared with other countries, and in particular America. The habit of American children of eating pea-nuts might in part explain this discrepancy, but he believed that the condition was more common than was generally supposed, and this was more recognised in America than here. In a visit to Dr. Chevalier Jackson's bronchoscopic clinic in Pennsylvania University he had seen six cases in which Chevalier Jackson had removed foreign bodies from the lower air passages, whilst in 15 years in the ear, nose and throat department of the Edinburgh Royal Infirmary a like number only of such cases was recorded. A résumé of these six cases was given. The diagnostic signs were largely clinical, and most commonly the signs were those of a localised bronchitis. Atelectasis might be present. Chevalier Jackson described an asthmatoid wheeze which he regarded as diagnostic, similar to the wheeze of asthma but drier, the pitch varying with the size, position, and shape of the foreign body. It ought to be possible to make at any rate a tentative diagnosis without the aid of X rays, and X rays themselves were not infallible, because the foreign body might be non-opaque. With regard to technique, distal lighting had been developed by Chevalier Jackson, and had rendered the procedure much easier. A general anæsthetic was never used. Mr. Martin then described the technique of the operation, and gave the indications for it.

Referring to bronchoscopic treatment of bronchiectatic abscess, Mr. Martin said that the operation was comparatively simple and the relief to the patient amazing. There was always some pus left in the cavity even after very successful postural coughing. This residual pus was first of all evacuated by means of the suction bronchoscope. The cavity was washed out with boric, then dried and painted with absolute alcohol. The alcohol apparently set up a slight irritation and enabled the walls to seal together. One aspiration and lavage was not sufficient, though Chevalier Jackson reported one case in which a single aspiration had effected a cure. He considered the case, however, to be one of idiopathic bronchiectasis. The disappearance of the fœtor which followed aspiration was a great boon to the patient, and the operation did not upset him in any way. For vaccine therapy a swab could be obtained direct from the affected area, uncontaminated by the various organisms usually found in the mouth.

Mr. Martin's discourse was illustrated by lantern slides, and was followed by a discussion in which the President compared bronchoscopy with cystoscopy, and pointed out how the incandescent electric light had made this so much more practicable. There also took part in the discussion Mr. J. S. FRASER, Dr. R. A. FLEMING, Mr. DOUGLAS GUTHRIE (who showed some slides), Mr. J. D. LITHGOW, Dr. C. W. SOMERVILLE, and Mr. J. H. GIBBS, and Mr. MARTIN replied.

Mr. JOHN FRASER read a paper on

Problems of the Treatment of Empyema in Children.

With reference to the incidence of the disease, Mr. Fraser said that in the Royal Hospital for Sick Children out of roughly 1000 surgical cases about 15 were cases of empyema. A more important fact was, however, that the vast majority of those cases were secondary to infection of the underlying lung, and he thought it of interest to attempt to answer the question—what proportion of acute lung infections ultimately develop empyema? He estimated that

out of 49 cases of acute broncho-pneumonia the percentage was 14, and of 336 of influenzal-pneumonia, 5·7, an estimate which corresponded with the figures of Mounetier. A possible explanation was that broncho-pneumonia affected the more debilitated child, and that empyema was but an indication of a general want of vitality. On the other hand, the wider distribution of the broncho-pneumonia offered a greater opportunity for spread to the surface. Another point of supreme importance in the progress and conduct of the case was the nature of the infecting organism. In 53 pneumococcal cases the mortality averaged 6·9 per cent., whilst in 17 streptococcal cases it was 24·7 per cent. In streptococcal cases adhesions were few and the effusion widespread, whereas in the pneumococcal cases adhesions were many and relatively stronger, so that the effusion tended to be limited. This point was of great importance in considering treatment, for stereotyped treatment was to be deprecated. Points to consider were (1) the general condition of the child, (2) the type of infecting organism, (3) were adhesions present to any extent between visceral and parietal pleuræ? (1) and (2) were easily decided. With regard to question (3) the type of infection gave an indication, but was not a certain guide, nor were X rays infallible. Valuable information could be obtained from the amount of intra-pleural tension. A large-bore aspirating needle connected with a water manometer was inserted into the pleural cavity. The pressure varied within wide limits according to the amount of fluid present, but on the average it registered about 100 mm. of water. The important finding, however, was the degree of oscillation. In the absence of adhesions the play was wide, whilst the movement-limiting effect of their presence resulted in the maintenance of a constant pressure with comparatively little variation.

Mr. Fraser went on to discuss the practical details of treatment. In a case where adhesions had been demonstrated the aim was to open freely into the abscess cavity, to evacuate the pus, and also masses of fibrin adherent to the pleura, to establish a *closed* drainage from the most dependent part of the cavity, and to close completely the original wound after disinfecting its edges. Details of the technique were given. Dr. Fraser found that the results were most encouraging. After a period varying from 20 to 28 days the post-operative pneumothorax had disappeared, and the lung expanded to fill the cavity of the chest. In streptococcal cases free incision, owing to the absence of adhesions, led to extensive collapse of the lung, often with fatal result. Aspiration was, therefore, practised for four or five days to permit of the formation of adhesions, after which a procedure similar to the above might be applied with a considerable margin of safety. Every care must be taken to avoid breaking down the adhesions. Mr. Fraser considered this method superior to any other yet evolved.

Various points in the technique were illustrated by lantern slides.

The subsequent discussion was opened by the PRESIDENT.—Mr. D. P. D. WILKIE referred to the work of the commission on post-influenzal empyema in American camps, from which it was concluded that the best results were obtained from aspiration. He also spoke of the method of aspiration followed by injection of an amount of 1/2500 gentian violet equal to half the aspirated fluid.—Mr. W. J. STUART spoke of a method of suction drainage by means of a Politzer bag, which he had employed in adults with success.—Dr. S. DAVIDSON spoke of the importance of knowing the type of pneumococcus, and suggested the value of serum injection after aspiration.—Mr. J. W. DOWDEN, Dr. FERGUS HEWAT, and Mr. JOHN STRUTHERS also spoke, and Mr. FRASER replied.

Exhibition of Cases.

Sir NORMAN WALKER showed a case of leprosy. The patient was an old woman who had been in Russia 30 years before, but had had no communication with Russians even by post since then. She had apparently been perfectly well up till three years ago. Treatmen by a vaccine prepared from one of the nodules by Colonel W. Glen Liston was instigated with rather remarkable result, as shown by comparison of the present condition with a cast of the arm made before the commencement of treatment. Films made from the nodules before and after showed a remarkable diminution of bacilli since treatment. Some 20 injections had been given.

Mr. GEORGE CHIENE showed a case of snapping hip in a girl of 15 successfully treated by operation, and Dr. JOHN EASON showed a case of congenital heart disease in a woman aged 24.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING was held on March 6th, with Mr. G. P. NEWBOLT,[1] the President, in the chair, when Mr. HUGH REID read a note on an

Obscure Case due to Calculus

in the pelvis of an ectopic kidney situated below the brim of the bony pelvis. The case was seen by Mr. Reid while the patient was under the care of Mr. Thelwall Thomas in the Royal Infirmary. The patient, a man, had a history of cutting pain in the left lumbo-sacral region shooting towards the groin. He also had pain in the suprapubic region passing down the penis. Blood had been passed in the urine. The clinical findings were negative. Urine examination showed urea 1·97 per cent., a few blood and pus cells, and staphylococci. The X ray diagnosis was "stone in the bladder." At a cystoscope examination pus was seen coming from the left ureter and from this it was decided that the condition was due to a stone in a much dilated ureter, low down. An operation was performed by Mr. Thomas. A split-muscle incision over the left iliac fossa was made, the ureter was not found, and the kidney was then noticed to be placed entirely below the brim of the bony pelvis; the organ could not be brought out if its bed through the wound and the renal vessels were seen arising from the common iliac. The stone was felt in the pelvis of the kidney and removed. One month after the first X ray examination the patient was discharged with the wound healed after a normal convalescence. Mr. Reid exhibited a lantern slide of the X ray plate and gave a short review of the literature on the subject, together with an account of the embryology, clinical features, pathological changes, diagnosis, and treatment of ectopic kidneys.

Dr. MORRIS J. COHEN, who assisted at the operation, said that the presence of pelvic kidney was unsuspected. The right kidney was shown on the X ray plates in its normal position. The shadow of the pelvic bones would naturally obscure the outline of the left kidney. No pyelogram had been made. Recently he had seen a post-mortem of a female case in which the left kidney was fixed below the brim of the pelvis. In both instances the suprarenal bodies did not descend with the kidneys.

Dr. J. C. MATTHEWS read a note on two cases of

Hodgkin's Disease

showing the periodic pyrexia usually known as the Pel-Ebstein syndrome. In one of them the diagnosis of Hodgkin's disease had been confirmed by post-mortem examination. A condensed temperature chart, prepared on the lines suggested by Hall and Douglas, was shown. This showed a wave-length of about 21 days. The second case was observed over a much shorter period and showed a wave-length of about 14 days.

Dr. S. W. PATTERSON read a paper on 31 cases of the same disease. Having outlined the clinical features and pathological appearances of the blood-forming organs, he discussed the absence of any

[1] We recorded last week with regret the sudden death of Mr. Newbolt; an obituary notice appears on p. 626 of the present issue.—ED. L.

significant ætiological factor. Syphilis and tubercle were related to Hodgkin's disease only as secondary accidental infections. Three cases had been attending the skin department for chronic skin lesions, in one instance for six years, before severe symptoms of Hodgkin's disease appeared. The pathological changes in the liver and spleen had led by analogy with malignant disease to Hodgkin's having been regarded wrongly as a new growth affecting the blood-forming organs. Having regard, however, to the peculiar disturbances of temperature with remittances and big oscillations, the more or less progressive course ending in death, and the pathological appearances, the causative agent was likely to be parasitic.

Mr. J. T. MORRISON spoke of the uncertainty that prevailed as to the nature of the disease and even as to whether it was one disease or a group which was called lymphadenoma. In view of this he emphasised the importance of concentrating on what was known and of making the diagnosis as accurate as possible. He declared that no patient with an operable mass of glands in the neck should be condemned to the label lymphadenoma until a gland had been submitted to microscopic examination. In excluding tubercle this was most important. In regard to treatment, he declared that results of excision in early cases followed up by full courses of X ray treatment and arsenic were better than from any of these methods taken individually, and he pleaded for further trial of this plan.

Reviews and Notices of Books.

OPERATIVE SURGERY.

Covering the Operative Technique involved in the Operations of General and Special Surgery. By WARREN STONE BICKHAM, M.D., F.A.C.S., former Surgeon in Charge of General Surgery, Manhattan State Hospital; Instructor in Operative Surgery, College of Physicians and Surgeons (Columbia University). In six octavo volumes. London and Philadelphia: W. B. Saunders Company, Ltd. 1924. Vols. I. and II. Pp. 1726. 50*s.* net per vol.

THIS treatise on operative surgery, comprising in all nearly 6000 pages and 6300 illustrations, is most unusual in that it is the work of a single individual. Nowadays we are accustomed to systems of surgery and medicine, the results of the collaboration of a number of writers welded into a whole by a single editor. Here we have an immense work written throughout by a single author, free from overlapping, unevenness, and other short-comings of a collective system, and with uniformity of outlook and expression. The author can only have achieved this success by colossal industry and a tenacity which must surely have been strained almost to breaking point, when subjects in which he was not particularly interested had to be dealt with. The two volumes under review show no evidence of flagging in interest or effort. In the preface the author reveals the motives which led to the writing of such a book. It is intended to deal with operative technique alone, but the author does not over-rate the place of technique in surgery. He maintains that operations should be carried out with a consummate regard to technical detail, which should be unobtrusive to the onlooker. His object has not been to describe all the operations of surgery, but the work is almost encyclopædic; we find, for instance, four methods of performing the rarely undertaken operation of ligature of the innominate artery.

Vol. I. deals with general surgical technique, including anæsthesia, local and general, plastic surgery, amputations, and the excisions of bones and joints. Each operation has a systematic heading, consisting of (1) a description of the operative technique in a few words; (2) an anatomical designation of the structures involved; (3) the name of the surgeon or surgeons to whom credit is given for the invention or modification of the procedure. Each section begins with a general consideration of the region in question, including its surgical anatomy, while it is concluded by a paragraph labelled "comments." In this volume there are satisfactory accounts of the various amputations and excisions, whilst some subjects to which much space is not usually allotted are fully considered. Amongst these is the question of the selection of the amputation site in relation to modern protheses, a full description of artificial limbs and what can be expected from them, kineplastic operations, and paraffin injections. The section on plastic surgery is very good, but, curiously, there is no mention of the method of the epithelial inlay graft, developed so extensively by Mr. Gillies.

In Vol. II. are found operations upon the blood-vessels, lymphatics, and nerves, operations upon bones, muscles, fasciæ, tendons, bursæ, cartilage, and joints (excluding excisions), together with two large sections upon the brain and spinal cord. This volume contains a mass of information, an immense number of operations being described, some of which are but little practised, such as Jonnesco's excision of the cervico-sympathetic, and Cushing's ventriculo-abdominal drainage for hydrocephalus. It is almost hypercritical to note an omission, but in the section on the closure of persistent bone cavities, amongst the ten methods discussed, no mention is made of the use of a pedicled muscle flap, which is very satisfactory on occasions. The sections on brain and cord surgery are unusually good.

The author set himself the purpose of describing technique only. One could wish that he could have amplified this by more discussion of the relative merits of the procedures he describes. Where he departs from this self-imposed restriction, unfortunately too seldom, his remarks are always valuable. For example, the lymphangioplasty of Handley and Kondoleon's operation appear in succession as apparently equal competitors for the surgeon's serious attention; the turning down of a section of nerve to bridge a gap and the implantation of a graft rank equally with direct union after slow stretching or the transplantation of the nerve trunk so that it follows a shorter course.

The author might have been more eclectic, even while professing only to deal with technique. But it was a great conception to write without assistance a large work dealing with all branches of surgical technique; in execution it has reached a pitch of extraordinary success.

The Students' Handbook of Surgical Operations. By the late Sir FREDERICK TREVES, F.R.C.S., and JONATHAN HUTCHINSON, F.R.C.S., Consulting Surgeon to the London Hospital. London: Cassell and Co., Ltd. 1924. Pp. 552. 10*s.* 6*d.*

THIS fourth edition of a well-known manual has been revised and enlarged by Mr. Hutchinson. The task has been thoroughly carried out, as can be readily seen by references to such sections as those on the stomach and skull. The author justifies the devotion of so much space to amputations and the tying of arteries on the grounds that these subjects bulk largely at examinations, as they provide excellent and almost the only available tests of the candidate's skill and anatomical knowledge. There is a very great deal to be said for the view whilst examinations are a necessity, and these sections do not seem to be over-emphasised in the present volume; more drastic revision of them would have detracted from the value of the work. The book is so well established that a detailed criticism is not required. It is likely to remain one of the best students' manuals on operative surgery.

ASSYRIAN MEDICAL TEXTS.

From the Originals in the British Museum. By R. CAMPBELL THOMPSON, M.A., F.S.A. London: Humphrey Milford, Oxford University Press. 1923. Pp. 107. 42*s.*

THIS compilation presents in 107 large plates the carefully drawn facsimiles of the text of 660 cuneiform medical tablets, for the most part hitherto unpublished,

from the royal library of Ashurbanipal, now preserved in the British Museum. This library is almost the sole source of our knowledge of Babylonian and Assyrian medicine, and it was discovered in 1849 by Sir Austin Henry Layard in the course of his excavations at the Mount of Kouyunjik, opposite Mosul, the site of Nineveh, capital of the later Assyrian empire. The tablets, dating back to the seventh century B.C., are, as Mr. Thompson states in his preface, copies of older texts, as is obvious from the similarity of the medical tablets found at Askur, which are centuries older. The reproduced tablets, some of which are mere fragments, are arranged and indexed. No translations are included, but many of the texts are interpreted and systematised by Mr. Thompson in a paper, published in the Proceedings of the Royal Society of Medicine, 1924, Vol. XVII. (Section of the History of Medicine), pp. 1–34, of which reprints [1] are available. It is a little over ten years since the late Prof. Morris Jastrow of Pennsylvania lectured to the Royal Society of Medicine on the medicine of the Babylonians and the Assyrians, and his address [2] is still worth reading.

MODERN METHODS IN THE DIAGNOSIS AND TREATMENT OF GLYCOSURIA AND DIABETES.

Second edition. By HUGH MACLEAN, M.D., D.Sc., M.R.C.P., Professor of Medicine, University of London, and Director of the Medical Clinic, St. Thomas's Hospital. London: Constable and Co. 1924. Pp. 191. 12*s*.

THE fact that the first edition of this book was exhausted within a few months certainly justifies the view that it has been of service to the general practitioner. Opportunity has now been taken to add a special chapter on the properties and use of insulin. The discovery of insulin by Banting is described, and a short account is given of its preparation and standardisation. The effect of the drug on normal and diseased persons is discussed, together with the symptoms and treatment of hypoglycæmia. The type of patient with diabetes mellitus who needs insulin is described, and the necessity of making certain of the diagnosis before starting treatment is insisted on. Prof. MacLean is pessimistic as to the ultimate benefit which insulin will confer on patients, since with the old dietetic treatment patients who had done well at first relapsed afterwards. He expresses the opinion that insulin will do no more to cure diabetes than does thyroid extract to cure myxœdema. But no one outside certain irresponsible writers in the press has ever hoped that a real cure would be obtained, however great the improvement might be both in the clinical condition and in the recovery of sugar tolerance.

The general directions for the giving of insulin to patients are clearly set out, and certainly with their help there should be no symptoms of overdosage, even if no blood-sugar determinations are carried out. The importance of blood-sugar determinations is, however, pointed out. The observation that mild infections play an important part in lowering the sugar tolerance is well known, and must not be overlooked. The directions given for the treatment of coma are simple and good. The rest of the book has been little altered. In our review of the first edition we pointed out that references to some of the literature on the subject would add greatly to the value of the book. In the new chapter on insulin no reference is given to any recent work or papers; and although Prof. MacLean in several places notes his disagreement with certain opinions which have been expressed, he omits to give either the name of the authors or the references to their papers.

The book will continue to be much read and appreciated by the practitioner, for it describes the physiology and pathology of diabetes in simple language and gives a good account of insulin therapy.

X RAYS AND CRYSTAL STRUCTURE.

Fourth edition, revised and enlarged. By Sir W. H. BRAGG, K.B.E., M.A., D.Sc., F.R.S., Director of the Royal Institution of Great Britain and of the Davy Faraday Laboratory, Honorary Fellow of Trinity College, Cambridge; and W. L. BRAGG, F.R.S., Langworthy Professor of Physics in the University of Manchester. London: G. Bell and Sons, Ltd. 1924. Pp. 322. 21*s*.

THE authors have found it necessary to rewrite a great part of their original book on this subject. Since the discovery by Laue in 1912, that the regularity of structure of crystals could do for X rays what a diffraction grating does for light, a new branch of physics has developed. This allows us not only to determine the wave-lengths of beams of X rays, but, by means of the knowledge which has been gained on X ray wave-lengths, the view is encouraged that many of the details of crystal structure will be revealed by an analysis of the X ray spectra which the crystals produce. The authors have contributed largely to the advances in this subject and the X ray spectroscope of their design is now found in many laboratories. The general arrangement of the book is unaltered, but the subject-matter has grown apace; perhaps the most interesting development is the experimental attempt to reveal the structure of organic crystals by means of X ray analysis; among the organic substances so far investigated on these lines may be mentioned naphthalene, anthracene, benzoic acid, resorcinol, urea, and tartaric acid. The book finishes with an appendix of 15 pages, giving a list of all the crystal substances which have been submitted to X ray analysis.

It is attractively written and well illustrated with photographs of original line drawings, which help the reader considerably in visualising crystal structure.

ENDOCRINOLOGY.

The Endocrine Organs. An Introduction to the Study of Internal Secretion. Part I.: The Thyroid, Parathyroids, and the Suprarenal Capsules. Second edition. By Sir E. SHARPEY SCHAFER, M.D., F.R.S., Professor of Physiology in Edinburgh University. London: Longmans Green and Co. 1924. Pp. 175. 15*s*.

THE first edition of this book has been out of print now for about four years, and we extend a very hearty welcome to this the second edition. It is to appear in two volumes, of which this is the first. There is no doubt that it is one of the best books on the subject in the English or in any language. Certainly in no other work is the vast literature treated with such a masterly skill; the best of the literature has been collected and given in footnote references, and the labour this has involved must have been immense. Moreover, the literature has been brought well up to date. Sir Edward Sharpey Schafer has rendered to physiology and to medical science in general a very great service in putting the salient facts of this important branch of knowledge within easy reach of anyone who really wants to know what are the ascertained facts on internal secretion. While the matter has been considerably extended and many additions made to the illustrations, the general technical excellence of the publication is well up to that of the first edition.

An Introduction to the Study of Secretion. By SWALE VINCENT, M.D., F.R.S. Edin., Professor of Physiology, University of London (Middlesex Hospital Medical School). London: Edward Arnold and Co. 1924. Pp. 168. 10*s*. 6*d*.

THIS volume represents in slightly expanded form the matter of eight university lectures given at the Middlesex Hospital during last winter. It might well have received the sub-title "Essays of a Sceptical Physiologist," for its author clearly shows that scepticism is much preferable to improperly founded

hypothesis. One of the main objects of the book was "to examine the main facts of secretion and 'internal secretion' to see how far they may legitimately be included in a common category." The results, so far as they are sufficiently definite in the present state of our knowledge, indicate that the two functions are essentially different. We agree with the author's conclusions, and would be glad to see the book widely read, not only by physiologists but also by senior students and by those interested in organotherapy. On the last-named subject the author is very sceptical, the position of course being reached that while he prefers fact to hypothesis, he has to decide what and where a hypothesis is tenable. Individual opinion cannot here be final.

Lectures on Endocrinology. By WALTER TIMME, M.D., Attending Neurologist, Neurological Institute, New York; Professor of Endocrinology, Broad Street Hospital, New York. New York: Paul B. Hoeber, Inc. 1924. Pp. 123. $1.50. (A Reprint of an article which appeared in the *Neurological Bulletin*, January, 1921.)

THIS is a little book which takes conclusions regarding endocrinology as far as is really safe in the present condition of knowledge. Many interesting cases are described and illustrated with photographs. On the purely scientific side there is less to be said in favour of the book, for, as in many works on this subject, unjustifiable arguments are used to fill the gaps in our knowledge. But as the work is intended mainly for clinical readers there can be little objection to it on those grounds.

MARRIAGE AND SYPHILIS.

By G. M. KATSAINOS. Boston: Wright and Potter. 1923. Pp. 162.

THE campaign for the eradication of venereal disease was won the day that "syphilis" appeared in the headlines of a respectable newspaper, but the victory needs to be pushed home in every possible way. Dr. Katsainos proceeds along the blood-curdling line, and by his descriptions and pictures of the most extreme results of congenital syphilis will impress some, but he will offend the moderate by his exaggeration, medical men by his accusations of indifference and carelessness, women by his frank conclusion that they are unfit for the medical profession because they do not understand syphilis. They will perhaps forgive him for his real sincerity in the best of causes.

PAPERS ON PSYCHO-ANALYSIS.

Third edition. By ERNEST JONES, M.D., M.R.C.P. Lond., President of the International Psycho-Analytical Association and of the British Psycho-Analytical Society. London: Baillière, Tindall and Cox. 1923. Pp. 731. 25*s*.

THESE are chiefly papers read before various societies, and, though not arranged in chronological order, indicate the growth of the complexity of the subject. The order gives an impression of unevenness; the fourth chapter plunges the reader into an account of recent advances in psycho-analysis for which he is scarcely prepared, and the chapter answering criticisms of psycho-analysis would be better placed early in the book. Five chapters are new and replace an equal number now omitted. That on the nature of auto-suggestion has been called forth by the need for examining this current explanation of mental phenomena, and the author, like everyone who attempts a serious examination of suggestion, finds definition difficult. One gathers that he recognises both auto- and hetero-suggestion: the former depends upon a primary narcissism, aided by the primitive belief in the omnipotence of thought, whilst if the ego-ideal is resolved into the earlier father-ideal—that is, if the subject reverts to an infantile attitude towards the suggestor—the process may be termed hetero-suggestion. He regards it as impossible to combine suggestion with psycho-analysis. Of the older chapters one, dated 1909, describes a case of wandering associated with loss of memory, and it is to be noted that, although such cases seem to be frequent, the fact that the patients are amenable to treatment directed to the restoration of the lost memories is not yet part of our common knowledge.

The new-comer to the subject will find some papers easy and others almost beyond his grasp, but the appearance of a third edition shows that the book is able to compete successfully with less authoritative works which would present us with a "psycho-analysis without tears."

MIND AS A FORCE.

By CHARLES F. HARFORD, M.A., M.D. London: George Allen and Unwin. 1923. Pp. 128. 3*s*. 6*d*.

Dr. Harford makes no pretence to represent any but his own views, though his chief theme is the method of treatment associated with the name of Mr. Coué. He is somewhat naive in making apparently simple postulates which lead to sad complications. Mind is a force, he says on page 17, and a few pages later we read of a new memory being added to the "store chambers of the mind." This puzzle, like the identification of conscience with the Freudian "censor," should set psychologists thinking. The claim that micro-organisms, chemical poisons, and the like must operate through some influence of the mind is likewise stimulating. His explanation of the "law of reversed effort," however, emphasises a phenomenon often overlooked by those who regard the neurotic sufferer as a person who only needs to exercise "will" in order to get well. He has expressed a clinical fact, too often ignored, in the following words: "To attempt to counteract the evil tendency of the strong emotional force in the memory by a counter-charge of emotional force exercised by the will leads to a deadlock or reverse." The author is evidently a religious man with a charming tolerance and a persuasive manner of writing. One pictures him as easily attaining a personal influence over his patients which, in spite of his own theories, is probably more effective than any auto-suggestion. The book is, as indicated above, not a sound guide to theory, but it carries a suggestion of restfulness often lacking in psychological literature, and, whether written for the purpose or not, could be safely, and perhaps with benefit, placed in the hands of many neurotic patients.

JOURNALS.

QUARTERLY JOURNAL OF MICROSCOPICAL SCIENCE. Edited by Prof. GOODRICH, F.R.S., and others. Vol. LXVII., Parts 3 and 4. Oxford University Press.—These two parts deal with a variety of zoological topics representing nearly the whole range of the practical aspects of the science. There are 11 separate memoirs, all of interest. Dr. Woodland has continued former studies upon the structure of the monozoan cestodes, a group probably serving to connect the older cestodes with the corresponding group of trematodes, which latter is entirely "monozoan" and never forms indefinitely multiplying chains lying in contact like the familiar forms of cestodes. Another paper, dealing also with the general anatomy of a species, is that by Dr. Agersborg, of Williams College, Massachusetts, upon the Nudibranch *Melibe leonina*. It is a comprehensive memoir illustrated by 11 double plates and containing a full bibliography. Among the lower forms of life the fairly well known infusorian, originally described by Ehrenberg, and named *Spirostomum ambiguum*, is dealt with by Miss Bishop, who has specially studied the meganucleus and micronuclei which are abundantly figured in two plates. Other protozoa form the subject of papers by Prof. Bronte Gatenby and Miss King (The Golgi Bodies of a Coccidian), while Mr. J. S. Huxley and Mr. de Beer write upon "Dedifferentiation" in Campanularia and Obelia by resorption of the hydranths wholly or mainly into the stem.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XII.—PUBLIC HEALTH APPOINTMENTS.

BY G. S. ELLISTON, *M.C.*, M.A.,
BARRISTER-AT-LAW; EXECUTIVE SECRETARY, SOCIETY OF MEDICAL OFFICERS OF HEALTH.[1]

"I am as poor as Job, my Lord, but not so patient."—*Henry IV.*, Pt. II., Act 1.

A CERTAIN liveliness which has been noticeable in connexion with public health appointments during the last five years is perhaps not wholly understood by private practitioners or by young graduates who are considering the pursuit of preventive medicine as a career. It may be useful, therefore, if we consider here the conditions at present obtaining in the public health service and the policy of the British Medical Association and the Society of Medical Officers of Health in regard thereto.

Evolution of the Public Health Service.

For some reason which is difficult to explain the remuneration of public health appointments has never yet borne any reasonable relation to the earnings of practitioners in other branches of medicine. In spite of this fact many good men were attracted to a service which offers unique opportunities of advancing the well-being of the community. The work accomplished by these pioneers during the last half-century met with scant recognition, although the results they achieved brought about a spectacular reduction in morbidity and mortality. Of recent years there has been legislation involving a remarkable extension in the provision of public health medical services, and the men who had been mainly concerned with environmental hygiene, found themselves responsible for the medical supervision of school-children, the welfare of mothers and infants, the organisation of clinics for the treatment of defects and minor ailments, and the administration of schemes for the control and treatment of tuberculosis and venereal diseases. It was when they realised how closely the public health department must be brought into contact with the private practitioner that medical officers of health became uneasy about the staffing of the service. While they had been content to accept almost contemptuous salaries themselves, it dawned upon them that for the extended activities of their departments they must have assistant colleagues of good standing who would command the confidence of the public and the respect of the private practitioner. It meant, in fact, that in order to attract and retain such assistants, the service must offer salaries comparable with the rewards of other branches of practice. Thus it happened that a campaign for fair salaries in the public health service has been initiated and carried through mainly by senior medical officers of health who can expect no personal gain from the result of their efforts.

Staffing of Health Departments.

The majority of the medical officers[2] who have chosen the public health service as a career are real enthusiasts, and if they magnify their office it is because they fervently believe that the future belongs to preventive medicine. But they know well enough that the influence of the health department cannot reach its maximum until every private practitioner is coöperating for the prevention of disease. Hence their anxiety to attract promising young graduates to the public health service, men with qualifications and experience that will secure the confidence of their colleagues in private practice. They would like it to be recognised by the medical schools that the extension of preventive medicine calls for the best brains of the profession, more especially as the health officials in their relation to local authorities can do much to instruct lay opinion on medical matters. It is not enough, however, to offer a young doctor work of extraordinary interest and influence; if he is to accept the limitations of an official post he is surely entitled to an adequate salary with reasonable prospects of advancement. Otherwise the public health service must be staffed by men with private means, by men with no ambition, or by men who have failed in other branches of practice.

Before the great extension of health services there were so few assistant medical officers of health that all of them might expect to secure promotion to a principal post in the course of time. To-day things are very different, for in the counties and big cities, in addition to deputy or assistant medical officers of health for general administrative purposes, there are assistant medical officers for specialist branches dealing with tuberculosis, maternity and child welfare, school-children, bacteriology, or venereal diseases, and clinical medical officers for ear, eye, nose, throat, and skin defects and minor ailments. Obviously, only a small percentage of these assistant medical officers can become medical officers of health, and a principal consideration with the Society of Medical Officers of Health has been to devise a graded list of appointments that would encourage experienced men to remain in the service. It should be recognised, therefore, that we have now in the public health service two types of assistant, although in the smaller areas one medical man may combine the duties of both. But it seems likely that the types will become more and more distinct as the organisation of the public health service develops, so we may consider here the training and experience which should be expected of candidates for these posts.

Assistantships in the Service.

Administrative Posts.—The young medical graduate whose ultimate ambition is to become a medical officer of health, has several years' work ahead of him before he should seek his first appointment. Under the new regulations of the General Medical Council it will take him two years to acquire his D.P.H. or other specialist qualification in State medicine. For a further period he should hold resident appointments in hospitals for women and children, and for the treatment of ear, eye, nose, throat, and skin affections. All this in order that later on he may be competent to administer the various health schemes of his local authority. It is also advisable that he should serve for six months or so as assistant to a busy general practitioner, so that he may realise the difficulties to be contended with in that field. The head master of Westminster School lately urged[3] that there should be no hurry or impatience in the education of the young doctor, whose training must necessarily be more prolonged than in the case of other learned professions. The head master indicated 27 years as the age when the public began to feel confidence in a private practitioner, and it is about that time the average graduate is ready for his first appointment in the public health service. Even then he should extend his experience by entering as a resident medical officer at a municipal fever hospital or tuberculosis sanatorium. It will be seen, therefore, that the medical man who wishes to equip himself thoroughly for the highest administrative posts in the public health service will not have completed his full training much before his thirtieth year.

Specialist Posts.—Although a public health qualification is not essential for those entering specialist branches of the service it is very desirable, for even

[1] Although an official of the Society of Medical Officers of Health, the writer of this article accepts sole responsibility for the statements set out here, which represent his own interpretation of the considerations which brought about the movement for a scale of salaries for the public health service.

[2] Throughout the article all references to medical officers apply equally to men and women practitioners, it being understood that there should be equal remuneration for both sexes.

[3] Brit. Med. Jour., March 8th, 1924, p. 438.

the clinical activities of the health department should be based on the general scheme for the prevention of disease. Beyond this point he will follow the usual course of training for his particular branch of work by residence and attendance at the appropriate special hospitals. If he is wise, and if he hopes to attain a senior post in the public health service, he will take one of the higher qualifications in medicine or surgery, for the value of the specialist medical officer depends very much on the confidence he inspires amongst the private practitioners in his area. Hitherto these posts have been so badly paid that the claims of the men appointed to be regarded as specialists have sometimes been very slender, so that the experienced general practitioner has felt no great respect for suggestions coming from the public health department. It was in order to attract highly qualified men for these clinical posts that the Society of Medical Officers of Health decided it was necessary to grade these appointments and to offer them reasonable prospects of advancement on the lines indicated below.

Minimum Commencing Salaries.

We thus arrive at the necessity for a minimum commencing salary for medical men entering the public health service. The Society of Medical Officers of Health contend that highly-trained men are required for these posts and that the right type of candidate will be nearly 30 years of age before he is ready for his first appointment. The Society therefore recommended that the minimum commencing salary should be £600 per annum, on the understanding that entrants must have had three years' professional experience subsequent to obtaining their registrable qualification. This recommendation was approved and adopted by the annual representative meeting of the British Medical Association at Portsmouth last July, and advertisements offering less remuneration for assistant posts are no longer accepted by the professional journals. It is satisfactory to note that local authorities are realising that this minimum is a reasonable one, and over 20 assistant medical officers have been appointed at £600 since September last. In a number of cases the minimum has been resisted and, unfortunately, there have been applicants who were willing to accept the posts. On several occasions, however, the appointing authorities have not been satisfied with the restricted selection open to them on such terms, and the vacancy has been readvertised offering the recognised salary. Even when candidates are willing to seize an easy opportunity of securing a post, it is recognised by local authorities that their health departments lose prestige when appointments are not approved by the representative bodies of the profession.

Promotions and Increments.

It must be understood that the £600 minimum applies only to a junior assistant working under the medical officer of health, or under a senior medical officer. The latter category includes those medical officers who are in charge of departments (e.g., schools, tuberculosis, venereal diseases, maternity and child welfare, mental deficiency) and who are directly responsible to the medical officer of health, or, more rarely, as in the case of some school medical officers, to a committee. The minimum commencing salary for these senior medical officers is fixed at £750 when single-handed, rising to £1100 for those with six assistants, with increments of £50 for each additional two assistants. In the case of a deputy medical officer of health duly appointed to assist his chief in the general administration of the health department, the minimum commencing salary must be equal to 60 per cent. of the salary of the medical officer of health and not less than the salary of the next grade of medical officer in the department. Finally, we have the scale for medical officers of health commencing with a minimum of £800 in areas where the population is less than 35,000, and ascending by graded increases to £1800 for populations exceeding 600,000. The scale thus briefly summarised has been widely circulated by the British Medical Association with recommendations that the salaries indicated should be augmented by annual increments of 5 per cent., rising to 40 per cent. above the minimum basic rates, as an encouragement to experienced men to remain in the service. It is also understood that the above scale is not subject to reduction when the civil service bonus at present granted in many areas is reduced or withdrawn, such bonus being a definite addition to meet temporary economic conditions. An important principle embodied in the scale by the British Medical Association is that all public health salaries must be net, any expenses necessitated by the duties being paid by the local authority.

Enforcement of an Equitable Scale.

Those who are chiefly concerned believe that the adoption of this scale by the British Medical Association will have a marked effect on the enterprise and efficiency of the public health service. They believe also that the continuance of low salaries represented a real menace to the interests of the whole profession. This became obvious quite recently when the Ministry of Health, seeking to justify a reduction of the capitation fee for insurance practitioners, informed the Court of Inquiry that "for public health appointments men of superior qualifications, and in the case of medical officer of health appointments, men approaching middle age, can be secured for salaries in the neighbourhood of £800." In support of that statement the Ministry published a table showing that 97 principal posts had been filled in the three years 1920, 1921, 1922 by men aged about 39 at salaries less than £800 per annum.

The scale as now adopted is the result of nearly five years' work by a committee of the Society of Medical Officers of Health in frequent conference with representatives of the British Medical Association. It has received the sanction of the annual parliament of the profession, and it is being enforced with the invaluable and indispensable assistance of the professional journals. It was submitted for the information of the associations representative of county, borough, and district councils, who were invited to indicate any modifications which would make the scale more easily workable. It is much to be hoped that negotiations with these bodies will ultimately result in an agreement that will avoid disputes in reference to the terms of future appointments.

Meanwhile, it is the bounden duty of every medical man to support his colleagues in their efforts to place the remuneration of the public health service on a fair basis. It is not only the new entrants who are affected, but those already in office will benefit when the inadequacy of existing salaries becomes conspicuous in comparison with the pay of junior appointments. For quite obviously the enforcement of the new scale will be followed almost automatically by an adjustment in the payment of the whole public health service. Only one precaution is necessary for those who are not familiar with the scale,[4] they should apply for no public health appointment which is advertised only in the lay newspapers until they have inquired of the British Medical Association or the Society of Medical Officers of Health whether the terms are approved by those bodies. With loyal coöperation of this kind the attempts by local authorities to obtain cheap medical services will soon be abandoned.

[4] The scale was set out in THE LANCET, July 28th, 1923, p. 187.

MEMORIAL TO THE LATE DR. G. S. HART.—To memory of the late Dr. Hart, of Measham, a Dodge Motor Ambulance was dedicated on March 12th in the Market Square of that town in the presence of a large gathering of his former patients and friends. After the service Dr. R. Logan, of Ashby-de-la-Zouch, gave a memorial address and spoke in feeling terms of his late friend and colleague. The cost of the ambulance had been subscribed largely in the district, and former colleagues of the late Dr. Hart in Ulster had also contributed generously. Dr. Hart died in September of last year, and his death had been a great loss to the district.

MEMORIAL TO LORD LISTER.

THE memorial to Lord Lister, in bronze and granite, designed by the late Sir Thomas Brock and erected in Portland-place, London, W., was unveiled on March 13th by Sir John Bland-Sutton, President of the Royal College of Surgeons of England, in the absence, through illness, of Sir Charles Sherrington, President of the Royal Society.

Lord Hambleden, Deputy Chairman of the Executive Committee of the Lister Memorial Fund, opened the ceremony by outlining the history of the Fund. He said that very soon after Lord Lister's death in 1913 a committee was formed at the instance of the Royal Society and of the Royal College of Surgeons, with the object of commemorating the services of Lord Lister to science and to the alleviation of human suffering. That committee suggested that there should be in the first place a tablet, with a medallion and inscription, in Westminster Abbey; in the second place, a monument in London; and thirdly, the establishment of an international Lister Memorial Fund for the advancement of surgery, from which grants could be made for research and for distinguished contributions in surgical science, irrespective of nationality. A meeting was held at the Mansion House, and subsequently an appeal was circulated which met with response from all quarters of the world. Altogether, including interest, a sum of nearly £12,000 had been made available. The tablet had been placed in the Abbey for some time; and £5000 had been given to the Memorial Fund, which was in the care of the Royal College of Surgeons; and, finally, they had the statue. They were greatly indebted,

FIG. 1.

The Island Site in Portland-place, London.

he said, to Sir John Rose Bradford, hon. secretary, and Mr. F. A. Towle, assist. hon. secretary, for the very efficient administration of the business of the Fund.

Sir John Bland-Sutton then unveiled the statue and spoke as follows: "This memorial has been raised to the memory of a great surgeon, Lord Lister, who by his discoveries in science and his devotion to surgery united surgery and science, raised the art he practised, and launched it on the most wonderful era in its history. It is an honour to unveil this monument as a memorial of a genius who did so much to unveil the secrets of nature and taught surgeons safe methods for relieving men, women, and children from the dread consequences of septic infection. Veterinary surgeons apply the same principles when performing operations for the relief of physical suffering on horses, cattle, cats, and dogs. Lord Lister had the rare advantage of seeing his principles adopted by surgeons throughout the world. His influence will remain as long as surgery is practised as an art, and the principles he discovered will remain as a blessing on every race of mankind. He was inflexible in the pursuit of truth and may be described as patience personified."

FIG. 2.

The bust of Lister surmounting the memorial.

Lord Hambleden asked the Mayor of St. Marylebone to take the statue under the care of the borough council, which duty the Mayor accepted, on behalf of the present and future councils.

Among those present were:—

Sir Rickman and Lady Godlee, Sir William Lister, the Misses Lister, and other members of Lord Lister's family; Viscount Hambleden, the Mayor and Mayoress of St. Marylebone, Sir John Rose Bradford and Lady Bradford, Sir Frederick M. Fry. The Royal Society was represented by Lieut.-Colonel Sir David Prain, Mr. W. B. Hardy, and Mr. J. H. Jeans, Sir Arthur Schuster, Sir David Ferrier, Sir Frederick Mott, and Sir Arthur Keith; The Royal College of Physicians of London by Sir Humphry Rolleston; the Royal College of Surgeons of England by Sir John Bland-Sutton and several members of Council; the Royal College of Surgeons in Ireland by Sir William de C. Wheeler; the Royal Society of Medicine by Sir William Hale-White; the Medical Society of London by Dr. H. R. Spencer; the Lister Institute by Prof. C. J. Martin; the University of London by Mr. H. J. Waring; the University of Glasgow and the Royal Society of Edinburgh by Prof. F. O. Bower; the Glasgow Lister Memorial Committee by Lord Blythswood, Sir John S. Samuel, Prof. R. Kennedy, and Prof. Magnus Maclean. There were also present: Sir Charles Ballance, Sir D'Arcy Power, Sir Cuthbert Wallace, Sir Alfred Fripp, Sir Anderson Critchett, Sir G. L. Cheatle, Sir George Makins, and Mr. Henry Jones, a faithful servant of Lord Lister for 40 years.

WHIPPS CROSS HOSPITAL, LEYTONSTONE.—A reception on the occasion of the twenty-first anniversary of the opening of this institution will be held at the hospital on March 26th, when a conference, followed by a discussion, on Medical, Nursing, and Hospital Progress will take place. Dr. J. C. Muir and Mr. Thomas Smith, clerk to the guardians, will read papers.

THE LANCET.

LONDON: SATURDAY, MARCH 22, 1924.

ON INQUESTS AND AUTOPSIES.

MEDICINE as well as justice requires the accurate determination of the cause of death in all cases brought to the notice of the coroner. But in many parts of the country the lack of any provision for storing bodies is a real stumbling-block to this determination. The unsuitability for its purpose of the existing mortuary at Ipswich was brought to the notice of Parliament a few days ago by the representative of the borough, when the Under-Secretary of State for the Home Department was asked whether his attention had been drawn to the coroner's statement that he had been compelled to ask the proprietor of an hotel to allow a body to remain in the hotel until after an inquest on account of the unsatisfactory mortuary accommodation. Dr. A. H. BYGOTT, medical officer of health for West Suffolk, who recently brought the subject before the Royal Institute of Public Health, writes of the conditions under which post-mortem examinations are made in rural areas as being frequently disgusting. Twelve thousand post-mortem examinations are made annually by order of coroners, without affording proper means of instruction to medical students or for the collection of pathological knowledge. Dr. BYGOTT regards the viewing of the body by jurors as unnecessary; were this dispensed with, the body could be moved to a pathological department at some large centre, where pathological, chemical, and bacteriological investigations could be made. We agree that viewing the body is a small matter which might be abolished without harm, especially as many men and women see death for the first time when acting as jurors. The provision of mortuaries, however, at present rests with the local authorities, upon whom it is difficult to bring compulsion, for the Home Department has stated that it has no authority in the matter.

The Public Health Act, 1875, Section 141, states that the local authority may, or if required by the Minister of Health must, provide a mortuary, and Section 143 states that the authority may provide a post-mortem room, although there is no compulsion. Under the provisions of the Public Health (London) Act, 1891, every sanitary authority shall provide and fit up mortuaries, and if ordered by the county council must provide a most-mortem room, but no details are given for the staffing or provision of apparatus. Perhaps the question should have been addressed to the Minister of Health rather than to the Home Secretary. The condition of London mortuaries is good on the whole, although a year or two ago the post-mortem room attached to a mortuary (not associated with a hospital) was lighted only by fish-tail burners, and the only hot water available was from kettles. In country districts, where provision of mortuaries could not lightly be undertaken, the arrangements are often primitive; the pathologist may have to be content with the kitchen of an empty cottage near by. Doubtless the frequent reluctance on the part of coroners and doctors to holding post-mortem examinations is often due to this lack of accommodation. Regarding equipment, the London mortuaries are on the whole good, but in some respects are lacking. It often happens that there are no proper jars available if viscera are to be reserved for examination, and analysts frequently receive consignments in old jam jars or tins, tied up with newspaper and string, and unlabelled. It is doubtful if any of the mortuaries have apparatus for the preservation of material for bacteriological examination.

When it is considered necessary to hold an inquest it is equally necessary to hold a post-mortem examination in most cases, if the inquiry is to be satisfactory. And yet out of 5551 inquests collected from various parts of England, Dr. BYGOTT found only 2608 post-mortem examinations. Analytical and possibly bacteriological investigation may be desirable. A coroner has been known to decide against a post-mortem examination, although the issue was a choice between murder, manslaughter or suicide; such a decision may render exhumation necessary, and reopening of the whole proceedings. Directly or indirectly pressure is brought to bear on coroners to limit examinations with a view to saving expense, and also on doctors by relatives for this and other reasons. The provision of expert pathologists, analysts and bacteriologists is to be commended—if investigations were more thorough many more crimes would come to light—but there is little financial inducement to take up this class of work, and little encouragement to perform it thoroughly, when the law as it stands insists on experts being present at every adjourned inquest. In some cases the fee offered to the pathologist hardly covers expenses. The suggestion has been made to remove bodies to hospitals, at any rate in country places, so that a full investigation may be made. But as far as teaching hospitals are concerned, they already have sufficient material to keep their regular staff busy; the larger non-teaching hospitals may have a pathologist but no analyst, so that materials would still have to be sent to the public analyst. Only in exceptional cases does the Home Office intervene. Whether hospital pathologists would welcome continuous attendance at the courts on the present rates of remuneration is hardly doubtful; in country cases there would be the extra expense of transporting the body, and a longer call on the pathologist's time. With the suggestion that the functions of the coroner should be transferred to the medical officer of health we are not in agreement. The health officer has duties which bring him into contact with his fellow citizens in a variety of ways. For a semi-judicial inquiry of this type, it seems pre-eminently desirable to choose an independent person having no relation with municipal or other public duties, and not under the direction of a local council. We should like to see more whole-time coroners serving wider areas. That the coroner should be a medical man has always been advocated in our columns. If he is also a barrister so much the better, but if not any legal errors which he may commit, such as the transgression of the laws of evidence, are less important than medical errors, for legal errors can always be rectified in another court. Legal authorities have always opposed the holding of inquiries in camera, but in certain cases it might be desirable to admit only those persons who could give good reason for desiring admission, to the exclusion of the idly curious.

ADOPTION OF CHILDREN.

OVER 40 years ago New Zealand legislated for the adoption of children. Unlike the laws of ancient Rome, which mainly studied the provision of heirs for childless parents, the legislation of modern communities on this subject is chiefly concerned with the welfare of the child. New Zealand had realised that foster-parents can give the same care and affection to an adopted son or daughter as the natural parents themselves, and that, where this is the case, it may be advisable to give legal security to the relationship between foster parent and adopted child. Otherwise when a child has been removed from the control of unworthy and disreputable parents and placed with persons who give it proper care and often spend considerable sums upon its education, the original parents can disturb its well-being and its prospects by reclaiming it from the family in which it may be happily settled. Readers of Mr. KIPLING'S story "Friendly Brook" may consider his picture of the disreputable father blackmailing the family into which his child has been adopted to be uncomfortably close to the truth. Other countries have passed adoption laws similar to those of New Zealand. Possibly the war stimulated such legislation. Italy, at any rate, made special provision in 1919 for the adoption of war orphans. Since that year, within the Empire, British Columbia, Ontario, Saskatchewan, and Tasmania have passed Acts giving legal recognition to adoption. And now the Mother of Parliaments has before her at the present moment three Bills all dealing with the adoption of children and all emphasising the principle that adoption is not to be sanctioned unless it is likely to promote the welfare of the child.

Of these three Bills, Sir THOMAS INSKIP'S is the shortest, and therefore, in present Parliamentary conditions, the most hopeful. He would simply enact that parents or guardians may transfer their authorities and duties in respect of a child, subject to the approval of a county court or High Court judge. The Bill closely follows that of Mr. NICHOLSON which obtained a second reading in 1922, and that of Sir LEONARD BRASSEY presented in 1923, except that the adopter is no longer described by a harsh legal label as "transferee" of the child, and that the age-limit for adoptable children is raised from 7 to 10 years. The proposal contains the minimum. The other two Bills, one promoted by Sir M. MACNAGHTEN, the other by the DUKE OF ATHOLL, go into greater detail, much of which is common to both. They specify various conditions of adoption and various persons whose consent must be obtained. They do not restrict adoption to children under 10, but stipulate that if the child is over 12 its consent is necessary. They insist that the adopter must be at least 20 years older than the child adopted, and they prohibit marriage between the two. They allow the court to adjourn an application for adoption while permitting the child to be placed meanwhile with the proposed adopter, thus sanctioning a kind of temporary adoption on approval. Finally, while providing for registration, they make the records confidential. The DUKE OF ATHOLL'S Bill has special features. It has had a second reading in the House of Lords, and must be distinguished from the unpublished Scottish Bill introduced by the DUCHESS OF ATHOLL in the House of Commons. As befits a House of Lords measure, it proposes that adoption shall not affect the succession to any dignity or title of honour. It brings the adoptive relationship within the prohibited degrees already recognised by our marriage laws, and it extends the law of incest to adopted children—no doubt in recollection of a New Zealand case where an offender raised the defence that the child in question was an adopted child. The DUKE OF ATHOLL'S Bill confines itself to county court machinery and makes the county court judge's decision for most purposes final. It speaks throughout of "the child," and yet it contemplates the adoption of persons up to 21 years of age provided that they have no husband or wife living. The Macnaghten Bill, which is virtually identical with one presented by Mr. HURST in 1923, allows the abrogation of adoption for any good cause at the instance of the adopter, or the child (if over 16), or any relative or other person interested in the welfare of the child. If the court sanctions the abrogation, the parties are put back in their original positions as though no adoption had ever been made; if it is the adopter who wants the relationship ended, the court may insist on provision for the child.

The elaboration of detail increases the difficulty of draftsmanship. Sir M. MACNAGHTEN says a proposed adopter must be "of good repute," a happier expression than the original New Zealand stipulation that he should be "respectable." The DUKE OF ATHOLL in ampler phrasing would require him to be "a fit and proper person, having regard to all the circumstances, to have the care and custody of the child," and to be in a position and to intend to provide "suitable and proper maintenance and education as though it were his own child." If our county court judges are to be called upon to make the proposals work, they will appreciate the implied compliment to their abilities while conscious of the great addition to their already heavy duties. Competent observers of the working of the Adoption of Children Act in New Zealand, where the original provisions of 1881 were simplified in 1895 and have since been further amended in the light of experience, claim that it is a success from every point of view. It has been estimated that in a large proportion of cases the adoption orders relate to illegitimate children. The child benefits by obtaining a continuous home life, an environment equal to that of an ordinary legitimate child, and a proper chance of becoming a useful citizen. The adopting parents, perhaps childless, obtain a son or daughter whom they can regard and care for as their own. The State is relieved of the possible burden of maintaining the child. New Zealand makes provision for rescinding adoption orders in unsatisfactory cases, but it is stated that the percentage of these is very small. The social conditions and the legislative requirements of great pioneer communities overseas are not always identical with those of the home country; but England cannot afford to dispense with any measure which will better the welfare and the chances of children who will otherwise be neglected and handicapped unfairly in their upbringing. The association of illegitimacy with many deplorable and intractable conditions which come under medical notice, should ensure for a proper method of adoption the support of our profession.

THE EFFECT OF MATERNAL SYPHILIS ON THE DEATH OF THE CHILD.

AN investigation[1] of 1000 women of the hospital class in Glasgow has recently been undertaken just before, at, or immediately after labour, with the object of determining the incidence of syphilis in such women, of congenital syphilis in their children, and the effects of syphilis on the frequency of abortion,

[1] Child Life Investigation. Maternal Syphilis as a Cause of Death of Fœtus of the New-born Child. By John Norman Cruickshank, M.D., F.R.F.P. and S. Medical Research Council. Special Reports, No. 82. 1924. H.M. Stationery Office. 1s. 6d.

premature birth, and stillbirth. The work has been carried out for the Medical Research Council by Dr. J. N. CRUICKSHANK, and has evidently been painstaking and thorough. In the series of 1000 cases 9–10 per cent. gave a positive Wassermann reaction, and as a certain small number of cases admittedly fail to give a positive reaction in pregnancy, any slight error is doubtless in favour of the patients. This percentage corresponds with that of most recent observers in this field. Dr. CRUICKSHANK found that in practically every case (94 per cent.) the W.R. of the mother was in agreement with the reaction of the child at birth. He queries, however, the interpretation of a positive W.R. in the case of the new-born child: Is it the reaction of the child's blood—may it not be due to transference of the mother's reacting substances to the fœtal circulation? An investigation, carried out by Dr. H. C. BRUNNER[2] at a maternity hospital in Lausanne, brings out the fact that the Wassermann reaction is not very reliable in the diagnosis of congenital syphilis in the new-born. Among 150 new-born infants whose blood, taken from the umbilical cord at birth, was examined by the Wassermann test, there were only two giving a positive reaction, although at least six of the mothers were definitely syphilitic and Wassermann-positive. Curiously enough, in the only case in which the mother had contracted syphilis late in the course of her pregnancy, the new-born infant, as well as the mother, was found to be Wassermann-positive. A comparison of the Wassermann reactions in the mother and child in 113 cases of maternal syphilis of recent or old standing showed that it was positive in both mother and child in 50 cases, positive in the mother and negative in the infant in 35 cases, and negative in both mother and infant in 28 cases. There was not a single case in Dr. BRUNNER'S series in which this reaction was negative in the mother and positive in her infant.

As regards incidence of abortion, which Dr. CRUICKSHANK interprets as "birth of child before it was viable"—his figures prove no greater percentage of abortions in the group with positive W.R. over the group with negative results. Stillbirths were proved to be more frequent in syphilitic cases—18·07 per cent. as against 15·15 per cent. of non-syphilitic cases; and as he further demonstrates that a considerable proportion of the latter were sent into hospital with obstetric complications, almost inevitably causing death of the child, the figures could easily be made more striking if normal deliveries in syphilitic and non-syphilitic cases were compared. The incidence of premature births (after seven months) was vastly greater also in the syphilitic cases—32·5 per cent. of syphilitic cases as against 19·8 per cent. of non-infected women, and in this group of infected cases 38·7 per cent. had stillborn as well as premature babies. No relationship was proved to exist between ante-partum and post-partum hæmorrhage and syphilis, nor was syphilis found to be at all an important factor in the ætiology of eclampsia. In the cases which could be followed up for some months after delivery, a definitely larger percentage of infants with a positive W.R. died, compared with those non-infected. While not providing any strikingly new data on the subject, this independent and patient study of 1000 cases is well worth recording as confirmation of previous knowledge in a field not yet fully explored.

Annotations.

"Ne quid nimis."

TREATMENTS IN VOGUE IN GERMAN SANATORIUMS.

THE pooling of German sanatorium reports and their editing by Dr. H. Ulrici every year in *Beiträge zur Klinik der Tuberkulose* enable readers to ascertain in a few minutes what are the most popular therapeutic measures in German sanatoriums. Dr. Ulrici's latest review[1] covers the year 1922, and deals with the reports of 40 hospitals for diseases of the lungs. Considering how varied the treatment was, it is disappointing to find that only 15 per cent. of all the cases of "open" tuberculosis became sputum-negative during treatment. Perhaps one of the most important excuses for these meagre results is to be found in the shortness of the average duration of treatment; in as great a proportion as 84 per cent. of the adult male patients the duration of treatment was three months or less. Only 11 of the 40 hospitals practised artificial pneumothorax, 626 of 7068 patients suffering from "open" tuberculosis in the second and third stages being given this treatment. But whereas only 8·9 per cent. were treated by artificial pneumothorax, 26 per cent. were treated with some form of tuberculin. Ten different tuberculins or tuberculin methods were employed by these 40 institutions, and the three most popular methods, to judge by the number of patients treated, were Petruschky's, Ponndorf's and Much's (partial antigens). The least popular was Selter's "vital tuberculin," which was given in only five cases. Only 28 patients were treated with protein injections, whereas as many as 453 were given some form of chemo-therapy, the gold salt, krysolgan, heading the list with 289 cases. Sun-baths are, apparently, not yet popular in German sanatoriums, and only 1·7 per cent. of all the adult cases of pulmonary tuberculosis were given this treatment. Treatment with artificial light was much more popular, being given in 11·1 per cent. Of 2373 children, only 3·5 per cent. were given sun-baths, whereas 21 per cent. were treated with some form of artificial light. With regard to the results claimed for these various methods of treatment, even the most ingenuous and impressionable reader must be tempted to draw the conclusion that it is the nature of the disease rather than the nature of the treatment that determines the issue. Tuberkulomucin achieved good results in 56 per cent. of the first- and second-stage cases, and the same measure of success was claimed for old tuberculin, albumose-free tuberculin, and bacillary emulsion. Petruschky's tuberculin inunction was beneficial in 61 per cent., partial antigens in 65 per cent., artificial radiation in 63 per cent., and, in the case of children suffering from surgical tuberculosis, in 99 per cent. Until therapeutic claims are supported by an account of the exact nature of the disease and its activity in the patients cured, the sceptical will continue to doubt the efficacy of the *vis medicatrix hominis*.

A CLINICAL ANTHOLOGY.

INDIVIDUAL feelings as to the general value of anthologies vary. Some regard them as a superfluity; others may find in them a pleasant form of reading, which demands no great intellectual effort. Usually such compilations of other people's works are extracted from poetical or prose literature dealing with some particular aspect of life or nature. The application of this principle to medical books is a new idea which may well make an appeal to certain practitioners and students. Dr. W. F. Dutton has compiled an anthology[2] of intravenous therapy, which will be valuable for reference and will certainly appeal strongly to all those who intend to devote their lives

[1] Beiträge, 1924, lvii., 332.

[2] Intravenous Therapy. By Walton Forest Dutton, M.D. Philadelphia: F. Davis Co. 1924. Pp. 542. $5.50.

to attaining a special skill in this branch of medicine (or is it surgery?). The insertion of a syringe needle into a vein is an operation which requires much skill for its certain performance, and it will be encouraging to the intending specialist to find that so wide a field will be open to him. Several chapters are devoted to an account of the theory and practice of blood transfusion. Other subjects discussed at length are the use of arsenic compounds and intravenous anæsthesia. The second and larger part of the book deals with all the other conditions for which medicaments may be injected into a vein. These are arranged alphabetically and number no less than 108. All forms of treatment available for each condition are mentioned, as well as those that are more strictly intravenous. The book may be depended upon to give the most recent form of treatment available in each case. Thus the author emphasises the importance of the intravenous injection of caseosan for the various complications of gonorrhœa. The value of the book is enhanced by a number of excellent illustrations, some in colours, depicting the median basilic vein, the best method of constricting the upper arm with a bandage, and other points of importance. Dr. Dutton does not, as an honest anthologist, claim any originality for his book except as regards the idea. He is unable to find that any similar work has yet been published.

A DIET SCHEME FOR THE TROPICS.

THE special physiology of the white man in the tropics has recently been enlightened by two suggestive papers[1] from the pen of Dr. H. W. Kipping, of the Physiological Institute of the University of Hamburg. In these he points out that, apart from diseases, the great problem of the tropics is how to keep cool. The environment of the body cannot usually be much altered, but, within that environment, the temperature of the body is raised by work and food and lowered by sweating, which, however, gives little relief if the surrounding air is very damp as well as hot. It must be, therefore, our endeavour to avoid raising the body temperature, carelessly, without reason. White men are more liable than natives to heat-stroke, because they work harder and so raise their temperature more. Dr. Kipping gives instances of healthy European firemen whose body temperatures, when working in the fire-room during the passage of the Red Sea, rose to 101·5° F. The maximum safe output of work is, he thinks, a matter for calculation, being a function of the drying power of the air, its temperature, and its movement. But taking food also raises temperature, especially protein food; fats and carbohydrates exert less effect, and can be stored if taken in excess of immediate requirement. Proteins break up into amino-acids which, circulating in the blood, stimulate the tissues to increased metabolism, so raising the temperature of the body; this is their specific dynamic action. Since they cannot be stored, any excess taken in must be at once further broken down, whereby temperature is still further raised. Dr. Kipping concludes that in the tropics, proteins should be taken only sparingly during the hotter part of the day, the main protein meal being arranged to occur in the cooler evening. Where fruits are plentiful, the need for vitamins is supplied. Protein is more of a difficulty; 100 g., according to Voit, are required daily, but to get that from rice, for example, would compel the eating of five pounds daily, with a total caloric value of 5400, or about double what is required. The protein must not be supplied from a single source, as the right proportions of cystin, tyrosin, tryptophane, and the like, do not exist in every food. As to cellulose, Dr. Kipping holds strongly that there must be in the food some element, bulky, unabsorbable, and yet unirritating, to increase the mass of the intestinal contents and, by assisting peristalsis, to prevent constipation. This cellulose is easily obtained from fruits, salads, and bread made from coarse flour. After this evening protein meal, the office-worker can be quiet in a long chair, not further raising by muscular activity his temperature, already slightly raised by digestion. In Java, Dr. Kipping tells us, doctors not vegetarians in principle took to living exclusively on vegetable food. He puts forward himself the following scheme for food for a tropical day—Breakfast: tea or coffee, bread, butter, jam, pineapple or banana fritters, fruit. At midday: rice (not too much) with vegetables, salads, a little fish, fowl, or egg; all to be nicely cooked, but taken in small quantity. In the evening comes the main meat meal. The moral of Dr. Kipping's articles may be put briefly: Self-denial at lunch will keep you cooler through the afternoon.

GENERAL PARALYSIS IN OLD AGE.

Dr. Paul Carretti,[1] who has devoted his inaugural thesis to the consideration of the clinical aspects of general paralysis in old age, records 19 cases in patients aged from 60 to 72, including two which came under his observation in the service of Dr. Capgras in the Maison Blanche Asylum. The course of the disease is, as a rule, more rapid in old age than in earlier life, and remissions do not occur. Although there are a few instances on record in which senile general paralysis has lasted several years, in the majority of cases the disease proves fatal within 12 months. The interval between the primary syphilitic lesion and the appearance of the first signs of general paralysis is very variable and does not affect the course of the disease. In two of Dr. Carretti's cases the first symptom of general paralysis appeared 12 years after the chancre, which is the ordinary period in adult life, but more frequently the syphilitic infection had been contracted much earlier—namely, 30, 40, or even 45 years before. Only three of the present series occurred in women, a fact which shows that the influence of sex persists in old age. The symptoms consist in dementia with all the features of senile enfeeblement, such as diminution of memory for recent events, impairment of affectivity and judgment, relative preservation of consciousness of a morbid state and of the moral sense, frequent absence of delirium, and focal signs of dementia such as paraphasia and agnosia. The cerebro-spinal syndrome, which consists in abundant lymphocytosis, a positive Wassermann reaction, moderate increase of albumin, and slight diminution of the sugar and chlorides in the cerebro-spinal fluid is constantly positive and is a valuable guide to the diagnosis of the condition, which otherwise might be mistaken for ordinary senile dementia.

ZOOLOGY AND EUGENICS.

IN the last four or five years a good many zoologists have been interested in the application of their science to the welfare of mankind, and it is round this central notion that a diversity of essays has been collected into one volume.[2] Prof. Holmes writes well and interestingly on many topics—the present tendency of evolutionary theory, heredity and the mind, the biological fortunes of the negro, birth control, panmixia and degeneration, civilisation and natural selection. He has the usual chapter on "our deteriorating inheritance," and draws the usual gloomy picture of the college graduates who won't heed, and the degenerates who heed too much. But he differs from most writers on this well-worn theme in pointing out that, while it is useful to control the multiplication of the mentally defective, it is far more important that those who chide such prolificity should themselves be fruitful. A community, he says, can do alright with a few degenerates if it has also great men and women who really make a difference in the world; the chief danger at present is a uniform mass of dull mediocrity. Biologically his doctrine is sound enough.

[2] Studies in Evolution and Eugenics. By S. J. Holmes, Ph.D., Professor of Zoology in the University of California. London: Routledge and Sons. 1923. Pp. 261. 12*s.* 6*d.*

As is well known, though seldom stated, it is impossible to make any very great difference in the prevalence of recessive characters like mental deficiency by segregating those in whom they are manifest; disastrous combinations of unrecognisable heterozygotes would go on producing a supply for a very long time, even if all mental defectives were killed at sight. But a deliberate and concerted attempt by college graduates to furnish a due supply of proper persons is a much better heeding proposition because the failures, who are not exceptionally gifted, will, in nearly all cases, be at least tolerably good citizens. We would commend his doctrine to eugenic propagandists. His discussion of the insoluble negro problem suggests that increasing urbanisation and decolorisation, with a birth-rate falling faster than the death-rate, may soon lead to a decline in their numbers in America, and possibly to their practical extinction. The paper on infantile mortality draws attention to the curious fact—not, of course, newly observed—that whooping-cough is the one cause of death which kills more girls than boys. Males are the frailer sex. In early fœtal life there is a great excess of males which at birth is reduced almost to equality, and in the first few years of life changes to a preponderance of females. Some of the essays are slight—e.g., those on sexual selection and the effect of birth control on fertility. None is very deep, but none is meant to be. The book is intended for general reading, and people with very varied interests will read it with profit.

BISMUTH IN THE TREATMENT OF INTERSTITIAL KERATITIS.

IN a paper headed "Is Parenchymatous Keratitis Curable?" Dr. G. Kleefeld[1] has drawn attention to the modern high standard by which complete recovery from interstitial keratitis is judged, improved illumination and the corneal microscope betraying permanent flaws which more primitive methods of examination fail to disclose. Even when vision has been restored to normal, Dr. Kleefeld has never failed to demonstrate with the corneal microscope persistence of white patches and corneal blood vessels formed during the acute stage of the disease. At least this was the case before he began giving injections of bismuth. In one of his cases, given bismuth, the patient came under treatment in the early stage of œdema of the cornea. Vision was already reduced to finger-counting, although the duration of the disease was only three weeks. Injections of bismuth were given without any great hopes, but after eight days the œdema of the cornea had largely disappeared, only two or three small vascular bundles having succeeded in penetrating the cornea. The treatment was continued, and the œdema disappeared so completely that when the patient was examined three months later even the corneal microscope failed to show any lesion. It is probable that complete recovery can be effected by specific treatment only before or during the stage of œdema; when this has passed off the patient's fate is settled for better or worse. In a second case, in which one eye after the other was involved, the injection of bismuth aborted the evolution of the keratitis in the second eye after several injections had saturated the body with bismuth. In a third case, in which sulpharsenol had been given for a long time without any relief, and there were signs of glaucoma on the left side, the injection of bismuth was followed by the complete disappearance of ocular congestion, a return of the intra-ocular pressure almost to normal, and by diminution of the corneal opacity. Dr. Kleefeld gives little information as to the dosage of bismuth adopted in these cases, but he sounds the warning that bismuth may prove toxic to the optic nerve, and he therefore advises caution in the dosage till more is known of the affinity of bismuth for the nervous system. Hitherto the treatment of interstitial keratitis with mercury, arsenic, and iodides has been very disappointing, and if Dr. Kleefeld's favourable experiences with bismuth are confirmed, the outlook for this class of patient should be much better than it has been in the past.

MENTAL DEFECT IN EARLY CHILDHOOD.

ALTHOUGH the literature dealing with mentally defective children of school ages is abundant, little has been written about mental defect at an earlier period, at the time when these children are brought to the practitioner for diagnosis, and when appropriate treatment might yield the greatest benefit. The subject of the symptoms, diagnosis, and treatment of mentally defective children was therefore chosen by Dr. John Thomson for the course of Morison lectures on mental disease, recently delivered in the Hall of the Royal College of Physicians of Edinburgh. The clinical material on which the lecturer drew consisted in the notes of 1200 cases, 952 of which had been under 5 years of age. In the matter of classification, Dr. Thomson holds that of Dr. A. F. Tredgold to be the best of those which attempt to combine pathology with clinical findings. Cases are divided into two large groups: (*a*) Primary amentia, in which there is an original incapacity of the cerebral neurons for proper development; (*b*) secondary amentia, which are due to an arrest of development of the brain, usually at a later stage from some extraneous or accidental cause. Dr. Tredgold, dealing with children of school age, or older, includes 85–90 per cent. of the cases in the primary group and 10–15 per cent. in the secondary. Dr. Thomson's figures, referring to younger children, are: Primary, 57 per cent.; secondary, 43 per cent. The difference would appear to be due to the fact that many cases of primary amentia are not recognised till they go to school, and many of the secondary cases die in infancy. The recognition of mental defect depends on two things—information from the mother and the doctor's examination. The mother may give valuable information about the labour, about other children, or miscarriages, or about the family history. On examination, especially in severe cases, some abnormality of appearance or behaviour may be noticed, such as an abnormally small head or a too early closed fontanelle. The signs of an easily recognised disease such as mongolism, cretinism, or microcephaly may be present. Regarding behaviour, unnatural gestures and grimaces, such as rolling of the eyes, may betray mental defect. Lack of natural curiosity or abnormal emotional displays are morbid signs. A series of epileptiform attacks without apparent cause is probably an indication of the presence of mental defect. The persistent recurrence of attacks of petit mal is ominous, as it is often accompanied by arrest in the normal growth of the cranium. In these severe cases the prognosis is very grave. In dealing with the milder cases prolonged study of the child under various circumstances may be necessary before the extent of damage can be estimated and suitable training selected. The normally developing child first of all exhibits aimless movements of the limbs, which gradually become purposive as they become stronger. The instinctive movements, such as crying, swallowing, and sneezing, although they are purposive, unlike the random movements, are at first equally involuntary. In time they become clearly intentional, and the baby can be observed making efforts to turn his head and to reach objects. After the first three months he begins to balance his head. Later he struggles to sit up, turning his head to look about him, and practising convergence of the eyes. Still later, he exerts his will in learning to crawl, to stand, and at length to walk. In the same way the use of senses is gradually acquired and perfected. Another sign that the baby's brain is developing is the increasing gratification derived from the normal functions of the body. If for any reason these are interfered with, as from blindness or deafness, the growth of the intelligence is appreciably retarded. Later he learns to guide his movements more by the

help of his senses, and so adds to his knowledge of life. This leads by association of various observed events to the growth of memory. As some instincts and reflexes develop into voluntary actions, so others develop into emotions, and with the increase in number and strength of these the child's character is formed. Imitation of spoken words leads him to the beginning of speech, though understanding and application of words come later. Before he is a year old he understands much of what is said to him and uses a few words himself. Sometimes even after a few months he has some control over reflexes, and considerable control over bladder and bowel is reached in the second or third year. If this is not reached at 3½ there is some fault of development, health, or training. When he begins to sit up, controlled retention of saliva becomes necessary and in this he soon succeeds, except at such times as irritation from teeth or gums has temporarily increased its amount. Failure to show these normal signs in the absence of organic cause must be regarded as probably due to mental defect. "Bad habits," such as thumb-sucking, air-swallowing, rumination, &c., are of important significance. A habit of constantly protruding the tongue is often seen in mongols and cretins shortly after birth. These habits are generally just an exaggeration of the normal, and should be vigorously checked as soon as possible.

With regard to simple primary amentia, a number of cases now classified under this head will certainly with greater knowledge of them be distinguished and transferred to groups of their own. Consanguinity and neurotic heredity are important ætiological factors. Convulsions are common, occurring in 13 per cent. of the cases. The diagnosis is made more by exclusion than by positive findings. "Microcephalus," or the term which is often loosely used, is not a common disease, and in the true cases the lesion is a primary defect of the brain cells. The cranium is very small with a narrow receding forehead, a pointed vertex, and flat occiput. The fontanelle is closed at birth, or within 4 or 5 months—a symptom peculiar to this disease. The smallness of the head, which may escape notice at birth, becomes more noticeable as time goes on. There is no true paralysis, though exaggerated hypertonicity may suggest spastic diplegia. The features are usually well-formed and ears large and fairly normal, but the palate is unduly arched. The mental defect varies in direct proportion to the size of the head. Cerebral development proceeds very slowly. After the early years of apathy these children often become active, restless, inquisitive, and mischievous. Convulsions occur in more than one-third of the cases, but the cause is quite unknown. The brain resembles that of the higher apes, and the cells are imperfectly developed. The prognosis both as regards life and mental improvement is unfavourable. Mongolism was present in 25 per cent. of Dr. Thomson's cases under 5 years of age, and in 45 per cent. of those under 1 year. Many of them die in early infancy, mostly from catarrhal diseases. The protrusion of the tongue—a constant feature—would appear to be due to the shortness of the oral cavity rather than to undue size of the tongue. There are many signs of backwardness and imperfection in development. In disposition and character, although the infant may be rather dull at first, it soon becomes bright, cheerful, good-tempered, and affectionate. These children are especially apt at mimicry and, like cretins, cleanly and tidy in their habits. Of the congenital malformations, which are common, the commonest is congenital malformation of the heart, being present in 15·7 per cent. of the cases. The mongol has loss of powers of resistance to organismal infection, so that blepharitis is almost constant (over 90 per cent.). Their typical appearance makes the diagnosis easy. The prognosis is unfavourable both as regards life and mental improvement. Some perversion of endocrine development would seem to be an ætiological factor. A striking fact is that the average age of the mother was 37½ years. Thyroid treatment does not seem to be of much value. Sporadic cretins are much less common than mongols. The mental defects form a parallel with the well-known bodily defects, resulting from the faulty metabolism consequent on the absence of thyroid secretion. The diagnosis in doubtful cases can be rapidly settled by the striking improvement which follows on the administration of thyroid extract. Dr. Thomson holds that premature babies are much more liable than full-time infants to intracranial hæmorrhages. In diagnosis the history is most helpful, revealing a severe labour, prematurity, damage to the head apparent after birth, collapsed and asphyxiated condition of the child when born, or other suggestive information. The mental symptoms are mostly the same as those in other defective babies, although they appear worse in children with spastic muscles. The prognosis is more favourable than might be supposed, the restriction of movements often being overcome in time as a result of training.

In his concluding remarks Dr. Thomson laid stress on ante-natal work in the prevention of mental defect from birth injury.

THE DETERMINATION OF ACUITY OF VISION.

THE determination of the acuity of vision by test-types has been practised for over 60 years with but slight modification of technique. Snellen's type, in common use, is based on the assumption that the normal eye is capable of distinguishing the shape of an object the linear dimensions of which subtend an angle of five minutes, while its component lines subtend an angle of one minute, and that the acuity of those eyes which need a larger visual angle may be expressed as a fraction of the normal in proportion to the size of the angle required. It has stood the test of time, and no one has suggested any alteration in principle, but in the details of application it is not to be expected that no improvement is possible. Prof. John Green and Prof. A. E. Ewing have devised new optotypes[1] for which they claim three advantages. The first is that by grading the size of the different letters by geometrical progression the new test is made more scientific. The question, however, arises Is the advantage to be gained from it sufficient to outweigh the inconvenience of having to translate all records made by the old nomenclature into the new for purposes of comparison? The second advantage claimed for the new types is that they simplify the routine and enlarge the scope of trustworthy clinical determinations, by providing varied sequences and arrangements of the test-letters and other characters. Single letters diminishing in size have undoubtedly been found of practical value by shortening the time required for initial tests and so minimising fatigue on the part of the patient. With young children and illiterates it is impossible to utilise the type ordinarily found in our out-patient rooms. Various simple figures and pictures have been devised at different times to meet the difficulty. The trident devised by Snellen assumes more patience and intelligence on the part of the patient than is often forthcoming. For Prof. Green's characters, on the other hand, it is claimed that the vision of squinting children of 3 or 4 years of age can be accurately measured. Again, for mutes and deaf-mutes a page of type is provided upon which they may indicate the character or letter seen upon the test-card. The third advantage claimed is that the differences in the legibility of the several test-letters—a difference of which all experienced with ordinary test-type are aware—is minimised by appropriate choice of letters and a conservative change in the typographical character. We can recommend these test-types as a valuable addition to the consulting room, though we do not think they are likely to supplant those in ordinary use.

[1] Optotypes Consisting of Test-letters and Picographs for Measuring the Acuteness of Vision. By John Green, M.D., Professor of Ophthalmology in St. Louis Medical College; and A. E. Ewing, M.D., Emeritus Professor of Ophthalmology in Washington University. With 35 engraved plates. London: Henry Kimpton. 1923. 25s.

THE HEALTH OF HONG-KONG.

A REPORT on the health of the civilian population of Hong-Kong in 1922 is now available, and contains matter of interest. The population concerned is estimated at 662,200, of which total 15,200 are British and foreign civilians, the remainder being Chinese. The general death-rate was 25·16, for Chinese 25·47, and for non-Chinese civilians 20·46 per 1000. With regard to the chief prevalences of disease, plague heads the list with 1181 cases, as compared with 150 in the previous year; all of these cases but seven occurred among the Chinese population, and there was only one case among Europeans; 938 of the cases were notified in April, May, and June. Three species of the rat family are found in the colony, *Mus norvegicus* (the brown rat), *M. rattus*, and *M. musculus*, the respective percentages of the three forms being 41, 32, and 27. During the last nine years 85 per cent. of the rats examined and found to be infected with the plague organism were of the brown, and only 15 per cent. of the black species; the fleas known to be present are *Xenopsylla cheopis*, and *Ctenocephalus felis* and *canis*. Every precaution is taken to prevent rats from gaining access to buildings, such as provision of concrete for ground surfaces, and iron gratings for drains and ventilators, the use of kerosene emulsion for cleansing native dwellings every three months, and provision of covered metal dustbins; all buildings found to be infected are washed with kerosene emulsion, and clothing disinfected by steam heat. Rats probably enter the colony by means of shipping, especially in junks, of which "some four or five thousand would have to be dealt with"; a large organisation is therefore required.

Dr. J. T. C. Johnson, principal civil medical officer, who submits the report, discusses the question of the mode of transmission of leprosy. He considers that the infection is conveyed

"by some article of food, and the particular food which is in universal demand, wherever leprosy is found, is imperfectly cured or salted fish. At all times, and in almost every country where leprosy occurs, popular belief has associated it with the use of fish. Against this view it has been asserted that there are many races and peoples among whom leprosy prevails who do not eat fish because of religious scruples, or because they live in the interior of the country and are not able to get it. This has been abundantly refuted whenever the question has been thoroughly investigated. It has been asserted of India, Ceylon, Persia, Africa, but it appears to have been a statement based on preconceived opinion."

The Chinese themselves believe the disease to be contagious, and segregate such patients in leper villages. Dr. Johnson himself adopts the late Sir Jonathan Hutchinson's view, that leprosy is not contagious in the ordinary sense, and considers that the evidence for the fish hypothesis "seems to amount to a high degree of probability." He does not, however, refer to the possibility of infection through bites of insects, such as bugs and mosquitoes.

BY the death of Sir James Walter Mackay Simpson Bart., who died on March 16th in London, aged 41, the baronetcy conferred on his grandfather, the famous James Young Simpson, becomes extinct.

A SPECIAL meeting of Fellows will be held at the house of the Royal Society of Medicine on April 10th, at 5 P.M., to receive the medical officers of health who are visiting this country at the request of the League of Nations. Some 50 medical officers are expected, and Dr. Rajchman, medical director of the League of Nations Secretariat, will deliver a short account of the work of the League of Nations Health Organisation. The Minister of Health and Lord Parmoor, the British member of the Council of the League, will be present. The President of the Society, Sir William Hale-White, will preside. All members of the medical profession are invited to attend. Tea and coffee will be served at 4.30 P.M.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXIII.
INCREASING DEAFNESS IN ELDERLY PEOPLE.

IN "Rabbi Ben Ezra" Browning's picture of old age is much too optimistic. On the other hand, the Preacher in the twelfth chapter of Ecclesiastes is unnecessarily gloomy, as when he writes "all the daughters of music shall be brought low." Deafness is, nevertheless, one of the most common, as well as one of the most distressing accompaniments in the later registers of life; and it is the physician's duty to find out if anything can be done to alleviate it.

Criteria of Senile Deafness.

The first and most important step is to make quite sure that the patient is really suffering from senile deafness. In my experience the most common and most serious mistake is in making the assumption that because an elderly person is becoming deaf, the case is one of senile deafness. This mistake occurs the more frequently because the assumption has usually been made by the patient himself and by his friends. As a matter of fact, Eustachian and middle-ear catarrh are by no means uncommon in elderly people, and such cases may obtain very great relief by treatment.

The *age of onset* varies within comparatively wide limits. Senile deafness may begin as early as 60, or even before, or it may not make its appearance until 80. The onset is always gradual. A curious feature of the condition is the fact that the loss of hearing begins at the upper end of the musical scale, while the hearing for notes of low pitch is retained for a long time. Thus, frequently the first indication the patient has of his deafness is his inability to hear singing birds, especially the lark; whereas for the ordinary affairs of life, such as conversation, his hearing is as good as it ever was. As time goes on, however, the hearing power for the lower notes becomes affected and the deafness then becomes a serious trouble in the patient's life.

Absence of Tinnitus and Vertigo.—In uncomplicated cases of senile deafness the sufferer is almost always spared from the added burden of tinnitus or noises in the ears or head. This is a common and sometimes the most distressing symptom of ear disease, and it is perhaps remarkable that it is not an accompaniment of senile deafness. It must be remembered that tinnitus may occur in old people who are at the same time deaf. But here it will usually be found that the deafness is not of the uncomplicated senile type, but is associated with some other condition, such as the later stages of oto-sclerosis, which has been in existence long before the patient became old. It may also be due to arterial changes in the blood-vessels supplying the labyrinth, as in arteriosclerosis.

The sufferer from senile deafness is fortunately also spared, as a rule, from another common symptom of inner ear disease, vertigo. When this symptom is present the case is not one of uncomplicated senile deafness, but rather one of internal ear disease due to some constitutional condition such as arterio-sclerosis, or to some local change such as the deposition of calcareous salts in the vestibule or in the ampullæ of the semi-circular canals.

Rules for Differential Diagnosis.

The diagnosis of senile deafness is not difficult in uncomplicated cases if the physician will take the trouble to follow a few simple rules. On inspection through the aural speculum the presence or absence of wax in the meatus, or of the existence of suppurative middle ear can be determined. It is not uncommon to find milk-white deposits of calcareous salts in the tympanic membrane of elderly

people; and, indeed, they are sometimes found in younger individuals. They cannot be looked upon, however, as being the cause of deafness, for they may be found in individuals whose hearing is not appreciably affected. Their occurrence should be remembered by the physician, because if the tympanic cavity be inflated too violently, either by means of the catheter or the air-douche, the sharp edges of the crystals may tear the membrane and give rise to a perforation. Fortunately, such perforations heal rapidly provided antiseptic fluids or applications are not introduced into the meatus. Inspection may sometimes reveal the presence of indrawing of the membrane. But too much reliance must not be placed upon the position of the handle of the malleus, since this varies within fairly wide limits in individuals possessed of normal hearing. The same is true of the degree of opacity of the membrane, for this also varies greatly in normal persons. As already stated, elderly people suffer in particular from a loss of hearing for notes of high pitch. This is tested for by means of Galton's whistle. The hearing power for the low notes is ascertained by the employment of deep-toned tuning-forks, as these are the only instruments which give notes sufficiently free from overtones to be reliable. If the case is one of uncomplicated senile deafness in the earlier stages, the physician will be surprised how comparatively well these low notes are heard. In the late stages of senile deafness the patient loses the hearing for all notes unless they are sounded loudly.

Testing the hearing by bone-conduction is frequently of use in establishing a diagnosis. In cases of middle-ear deafness the patient hears the sound of a tuning-fork when held with its stem against the mastoid process, as long or longer than normal individuals. Where the deafness is due to internal ear disease—e.g., senile deafness—the fork when held in the position described is heard for a shorter time than is the case in those possessed of normal hearing.

Inflation of the Middle Ear.—But far the most important of the tests is that which is concerned with the effect of inflation of the middle ear. Not only is this a most important diagnostic matter, but it is at the same time an indication for treatment, and, in some cases, the most important means of treatment. Inflation of the middle ear, therefore, must be performed methodically in all cases. The procedure is as follows. Before inflation the hearing distance for the watch, the whispered voice, and the conversation voice must be determined and noted. Inflation of the middle ear is then undertaken. This must be done by means of the Eustachian catheter and with one end of the auscultation tube in the external meatus of the patient and the other end in that of the examiner. On no account must the physician trust to the effects of the air-douche associated with the simultaneous swallowing of a mouthful of water. Nor must he rely on the statement of the patient that "he has felt the air go up to his ears." The clear, unmistakable rush of air into the middle ear must be heard through the auscultation tube by the examiner, who must not rest satisfied until this occurs. Having assured himself that the middle ear has thus been thoroughly inflated, the hearing distances for the watch, the whispered voice and the conversation voice are again tested by the examiner, and the results compared with those found before inflation. If a definite increase in the hearing distance is found, then there is no doubt that the deafness is due, in part at least, to middle-ear disease; though, of course, disease of the inner ear may also be present.

Indications for Treatment.

The indications for treatment depend for the most part upon the result of inflation of the middle ear. If distinct improvement has occurred, then it will usually be found that some affection of the nasal cavities is present, such as chronic nasal catarrh, polypus, hypertrophy of the turbinated bodies, &c. These conditions must be treated by cauterising or by removal, as the case may be, but common-sense must be the physician's guide in this matter, and he must remember that the treatment must not be too heroic in old people. In mild cases simple treatment by sprays such as menthol in parolein (5 per cent. solution), &c., are sufficient. When the nasal condition is rectified so far as possible, the middle ear should be inflated by the catheter two or three times a week so long as improvement continues, which may be for several weeks. When no further improvement occurs the treatment should be stopped for the time being. It will frequently be found, however, that the dullness of hearing gradually returns. In such cases the inflations must be repeated every few months; the possession of their hearing means so much to them that elderly people are not only willing, but anxious, to have the treatment repeated. If, on the other hand, no improvement results from inflation of the middle ear the first time it is carried out, then nothing can be hoped for from that treatment by repetition. That is to say, if any benefit is to be derived from inflation it will be obvious from the first. In cases where no such improvement occurs the deafness is due to inner-ear disease, or less likely, to a middle-ear condition which cannot be remedied. In old people it will usually be due to true senile deafness. In these cases little can be hoped for by any line of treatment directed locally to the ear. The most that can be done is to try, by improving the general constitutional condition, to prevent the deafness from becoming worse, or at least to render its progress as slow as possible. If any local centres of septic infection are present, such as cystitis associated with enlarged prostate, these would naturally receive attention. Abundant hours of sleep should be advised, but these should be procured without resort to hypnotics, which usually have a bad effect upon the hearing.

Severe tinnitus is fortunately not common in the aged. When present, it is a most difficult condition to treat, and gives rise to great distress. The administration of bromides, at bed-time particularly, is quite permissible in these cases, because the patient would rather be free of the tinnitus even though the treatment involved some increase in the deafness. Furthermore, the tinnitus when severe is apt to interfere with sleep, and when this is the case a suitable hypnotic is desirable.

Artificial Aids.

When relief is not procurable by the means described above, the question arises whether benefit may be obtained by the use of one of the artificial aids to hearing. In regard to this matter, experience shows that so long as the deafness is slight in degree the patient prefers to do without these instruments. With increase of the deafness, however, many sufferers find them of great benefit, and are willing to make use of them. The kind of instrument to be recommended varies according to the degree of deafness. In cases where the deafness is great, then it will be found that the most useful type of instrument are those devised upon the principle of the telephone or microphone—e.g., the acousticon or acoustique. The chief objection to these instruments is the jarring brassy tone which they impart to the voice. So much is this the case that some individuals refuse to make use of them under any circumstances. For these sufferers the simple old-fashioned ear-trumpet is often quite effective if the deafness is moderate in degree, but is of little use in cases of great deafness.

AN INVESTIGATION INTO THE PRESENT HEALTH OF GERMAN CHILDREN.

BY HELEN M. M. MACKAY, M.D., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, QUEEN'S HOSPITAL FOR CHILDREN, AND INFANTS HOSPITAL, LONDON;

AND

M. D. MACKENZIE, M.D. LOND., D.P.H., D.T.M. & H.,
LATE SENIOR MEDICAL OFFICER, FRIENDS' RUSSIAN FAMINE RELIEF UNIT.

IN view of the contradictory reports concerning the health of children in Germany, it may be of interest to outline briefly the results of an investigation by the writers in Germany during February, 1924. Speaking broadly, it may be said that the conditions of child health in many German industrial towns bear numerous points of resemblance to those obtaining in Vienna in the post-war period, when for 20 months one of us was working in that city as a member of a unit sent out by the Medical Research Council and Lister Institute to investigate rickets in infants and young children. In the course of the present investigation the following towns were visited: Berlin, Leipzig, Munich, Mainz, Cologne, Essen and some of the smaller towns of the Ruhr, Breslau and the surrounding mining districts, Freiberg, Nuremburg, and Dresden.

Before describing the lines of inquiry, it is necessary to mention some of the difficulties of such an investigation. German economic and social conditions have changed rapidly, being successively affected by the privations of the later years of the war, by the partial famine conditions of 1919 and early 1920, by the period of recovery of 1921 and 1922, and finally by the disorganisation associated with the collapse of the mark in the autumn of 1923, followed by the present period of stabilisation. Each of these periods is reflected in the state of the children at varying ages in Germany to-day. Two of the principal difficulties in instituting any comparisons are: First, that statistics now obtainable in Germany have necessarily become imperfect and are not up to date; and secondly, that few of the statistics to which we have had access in this country are strictly comparable. Racial differences, the varying conditions in different parts of Germany, and among different classes of people, together with the different standards that exist in Germany, as compared with this country, in such matters as adequate clothing, &c., further obscure the real position.

The following were the lines on which the inquiry was conducted: (1) social investigation; (2) investigation of food consumption; (3) examination of the child; (4) evidence of malnutrition from disease incidence; and (5) general statistics.

Social Investigation.—This was largely outside our scope, but it is worth mentioning that the unemployment dole in Germany is about 7 or 8 Renten Marks a week for a man with a family, equivalent in buying power to a little over 7*s.* or 8*s.*, and the number of unemployed and partially employed is greater than in this country. It is obvious that this amount is insufficient for the maintenance of health, although one must remember that rents are often negligible.

Investigation of Food Consumption.—The most important factor in connexion with the food of small children is that milk and sugar have risen to twice their pre-war price, whereas flour is at about pre-war price. There is consequently a growing tendency to substitute flour and water for milk in their dietary. Moreover, owing presumably to the shortage of oil-cake, it was necessary during the war to reduce the official standard for butter fat in milk from 3 per cent. to 2·7 per cent., which still obtains. The milk production of Germany has dropped greatly, and is estimated at about 30 per cent. of the pre-war quantity. A still further shortage has resulted from the interference with the transport of milk from the country to the towns. This applies particularly to the Ruhr district, which in pre-war days imported a large proportion of its milk. Consequently, in many towns there is an absolute shortage of sufficient milk for the infants and children, whereas in others the milk-supply for these groups is sufficient, but the price is prohibitive, excepting for that supplied free or at reduced price for the use of infants, and in most districts for children up to about 2 years of age. Many children get sufficient calories, but suffer from improper balance in the diet. At the present time the brunt of the milk shortage appears to fall on children from 1 to 5; those under 1 year are, in general, receiving sufficient milk. Inquiry as to the food consumption in the preceding 24 hours is apt to be unsatisfactory, though by questioning large numbers valuable information may be obtained. Mothers tend either to exaggerate the want, or, in the majority of cases, are ashamed to say how little food they have had; and in the case of a child the tendency to repeat another child's statement or to say what he thinks is expected of him, is well known. Generally speaking, in every school that was visited, children in the higher classes were questioned, and of the hundreds of children examined the majority had meat only once a week, and margarine or other fat either for breakfast or tea. In some towns few of the children questioned had any form of fat on their bread. The midday meal generally consisted of black bread and vegetables, and in the poorest schools it was usual to find one or two children in each class who had had no food before leaving home in the morning.

Examination of the Child.—In order to examine unselected samples of the poorer child population, infant welfare centres, kindergartens, and schools were inspected in the poorest districts of each town visited, and the condition of the children with regard to physique, colour, amount of subcutaneous fat, evidence of tiredness—e.g., bad posture and dark rings under the eyes—and degree of activity were noted. From these observations the conclusion was reached that compared with British children, as known to us—i.e., in London and north country industrial towns—a low standard of health is more general in the towns we visited, and is to be found widely in children of all social classes—middle-class children are to be found in the poorest schools. We found no evidence of acute starvation in any group of children, except those of Breslau and the surrounding district. The condition of the children varies greatly from town to town—more stunting of growth was observed in the school-children of the Breslau and Essen districts than among any others. In some towns, such as Mainz, the overcrowding due to the large additional population caused by the occupation is probably a factor of great importance in producing the almost universal appearance of tiredness in the school-children.

Prof. Rudolf Martin, of Munich Anthropological Institute, has figures of great value concerning the physique of school-children, and has been able to institute a comparison between the heights and weights of Munich children in pre-war days, in 1921 and in 1923. Together with the heights and weights he has a large series of other measurements, and had hoped year by year to obtain data which would increase the meagre amount of knowledge now existing concerning the ultimate physique of children who had suffered from privation at varying ages. He excludes all children showing evidence of disease, for instance, rickets, so that no comparison is possible between his figures and those for children in English towns. His pre-war standard is taken from figures for about 12,000 children in Freiburg-im-Breisgau, Apolda, and Frankfurt-am-Main, and from comparison with pre-war Munich figures he has reason to believe that these figures also represent the Munich standard. His own measurements at the Anthropological Institute comprise several thousand children. Com-

pared to the pre-war standard, the 1921 standard in Munich was approximately 2–6 cm. less in height and 1–4¾ kilo. less in weight at each year of school age. Since there seems little doubt that the amount and severity of rickets have increased, the deterioration is greater than is shown by figures from which the diseased have been intentionally excluded. For 1923, on account of the poverty of the institute, Prof. Martin has only been able to obtain figures for children aged 6½–8½ years. The 6½–7½ year-old children show no significant change, but those aged 8–8½ years show a definitely poorer physique in 1923 than in 1921, the retrogression in 8½ year-old boys

FIG. 1.

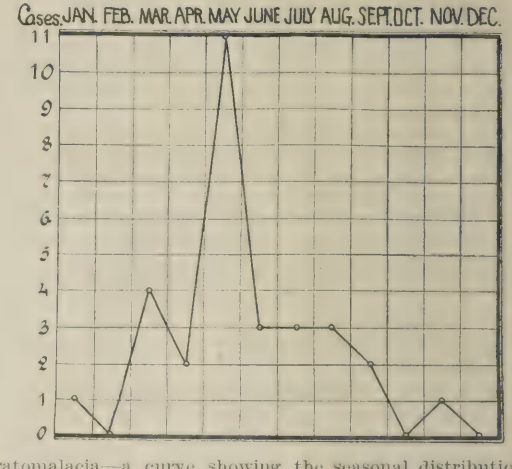
A case of hunger œdema following pure carbohydrate diet. January, 1924. The child is shown before and after treatment; the photographs were taken in the Breslau University Kinderklinik, and are reproduced by permission of Prof. Stolte.

being 4 cm. in height and 1·7 kilo. in weight, and for 8½ year-old girls 2·4 cm. and 0·9 kilo. respectively. Figures from Stuttgart and Mannheim show that in those towns, unlike Munich, the average heights and weights of school-children had risen by 1921 22 to approximately the pre-war standard, but no figures later than 1922 are available. An improvement from year to year between 1918 and 1921 can also be seen in the height and weight curves of Leipzig school-children. Prof. Martin's work would indicate a reversal of this process of improvement between 1921 and 1923, which is in accordance with the general impressions of nearly all medical authorities. On the other hand, the height and weight curves of the Leipzig school-children of 1918, 1919, 1920, and 1921 were, for almost all ages, better than the corresponding curves of Glasgow school-children for 1922–23. It must be remembered, however, that possible racial differences prevent any final conclusions being drawn from such figures. The so-called Rohrer index, $\frac{(\text{weight} \times 100)}{\text{height}^3}$, has been extensively used in Germany for purposes of comparing the standard of physical development attained by the children of different areas, and appears to be of value for mass work, but no similar figures exist in this country. Such weight-height indices seem of little use in estimating the condition of the individual.

Evidence of Malnutrition from Disease Incidence.

(*a*) *Nutritional Diseases.*—During the whole period of our stay in Germany only two cases of acute starvation were seen, both in the Breslau district. In this region a certain number of cases of hunger œdema in children of school age and under were admitted to hospital during the last few months, and similar cases were reported in Cologne (see photographs). No cases of hunger osteomalacia in adults were seen, though there were reports of a considerable number of such cases during the blockade period. Nearly all medical authorities are agreed that, as happened in Vienna, there has been a marked increase in the amount of rickets as compared with the pre-war period. This condition is, of course, due to defective hygienic as well as dietetic conditions, and therefore is to some extent an index of increased poverty. On account of the varying standards of diagnosis, general figures are of little value, but such figures as the following seem to indicate a very definite increase. In Schöneberg, a section of Berlin, 20·7 per cent. of all 6-year old children attending school now show evidence of rickets, according to the report of the school medical officer, whereas the corresponding figure for 1913 was 5·2 per cent. There appears to have been in some districts an increase of rickets in the present winter as compared with the winters of 1920–21 to 1922–23. For example, in the infant and child welfare centre associated with Prof. Rott of Berlin, 20 per cent. of the total children examined had evidence of rickets in the last quarter of 1922, and in the corresponding quarter of 1923 this figure rose to 40 per cent. Dr. Wendenburg of Gelsenkirchen in the Ruhr area, finds in breast-fed infants aged 3 to 5 months attending the welfare centres of the town, nearly 25 per cent. with craniotabes in the present winter. During the previous two winters, scarcely any craniotabes was to be found in such infants, but during the winter of 1919–20, when privation was severe, 50 per cent. had craniotabes. Keratomalacia is increasing in Germany after, we understand, an interval of comparative freedom since the blockade. Prof. Stolte, of Breslau University Kinderklinik, informed us that from the years 1912 to 1921 only 10 cases of this disease had been seen at his clinics, whereas 30 cases occurred in 1922, showing the usual increase in the spring months (see curve, Fig. 2). In Waldenburg (population

FIG. 2.



Keratomalacia—a curve showing the seasonal distribution of 30 cases treated at the Breslau University Kinderklinik, 1922. Reproduced from the paper by Dr. Richard Galka, Monatschr. für Kinderheilkunde, XXVI.

40,000) there have been 30 cases within the last few months, and cases have occurred in infants fed entirely at the breast, which presumably may be taken to indicate an extreme fat deficiency in the diet of the mothers. Cases are also reported during the past year in the University Kinderkliniks of Berlin and Leipzig by Profs. Czerny and Bessau. As was the case in Austria, there appears to have been an increase in infantile scurvy since the pre-war period, which is probably to be associated with the consumption of stale milk, and a few cases have occurred in breast-fed infants whose mothers were presumably also suffering from the disease. It may be of interest to compare the very heavy incidence of scurvy in Russia in young children in the year following that of the famine.

Diseases due to Lessened Resistance.

It is widely held that faulty nutrition has led to greatly diminished powers of resistance in children. No support for such a theory can, however, be found in the German statistics of deaths from scarlet fever, measles, diphtheria, or whooping-cough, all of which have shown a steady decline during the last decade. The death-rate from tuberculosis was roughly doubled in 1919 as compared with 1914, but fell steadily in 1920 and 1921, and showed a slight increase in 1923. For the third quarter of 1923 in the 46 largest towns the rate was 14·7 per 10,000 per annum. The London death-rate for the whole of 1922 was 12·8.

It is known, on the other hand, that an increase of tuberculosis is not immediately apparent in the death-rate, and there is a general consensus of medical opinion in Germany that tuberculosis has increased, particularly among children. It is quite impossible to get any reliable general statistics, but figures such as the following are suggestive: In Freiburg, in 1914, out of a total of 3178 students in the University, 10 were diagnosed as pulmonary tuberculosis; in 1922, out of a total of 3667 students, 93 cases of phthisis were diagnosed. Prof. Ranke, the well-known authority on tuberculosis, informed us that in 1922 of 4816 new cases attending clinics under his charge, 17 per cent. were suffering from open tuberculosis. In 1923, of 3209 new cases, 31 per cent. had open tuberculosis. In 1922, among school-children in Schöneberg, 0·4 per cent. were diagnosed as cases of tuberculosis of the lungs, as against 0·1 per cent. in 1913. It may be of interest to compare the figures for London County Council schools in 1923. Owing to the differing standards of clinical diagnosis no final conclusions can be drawn from them, although the difference is very marked—among 242,145 L.C.C. school-children 89 were diagnosed as definite cases of lung tuberculosis (i.e., 0·037 per cent., as against 0·4 per cent.).

In Berlin, out of 1000 infants 10 per cent. recently gave a positive tuberculin reaction, whereas formerly this figure was only about 3 per cent. Prof. Mayer of Munich gives almost exactly similar figures for his home for infants of 100 beds; the pre-war figure was 2–3 per cent., the present figure 10 per cent. Figures of increased attendances of cases of tuberculosis at individual institutions are apt to be misleading, as out of a total of 40,000 beds in tuberculosis hospitals and sanatoria 4100 have been closed on account of want of funds—therefore, no such figures are included in this paper.

We did not hear of any cases of cancrum oris. This is in marked contrast to the large amount of this disease seen in Russia during the famine.

Statistics.

The only general statistics of any value (apart from those already mentioned) are the general death-rate and the infantile mortality-rate. The death-rate for the 46 largest towns in Germany was lower in almost every month in 1923 than in 1922. The death-rate for the first quarter in 1923 was at the rate of 17·3 per 1000 per annum, and for the corresponding period in 1913 was 16·8 per 1000. The infantile mortality-rate has dropped considerably since before the war, though it has for years been higher than it is in this country. In the 46 towns previously mentioned there is an increase in the third quarter of 1923, as compared with the third quarter of 1922 (114 to 138). No later figures are available. In the last quarter of 1923 the infantile mortality-rate per 1000 in individual towns was: London, 67; Berlin, 124; Breslau, 148; Cologne, 106; Dresden, 93; Frankfurt, 71; Munich, 117.

The improvement in the infantile death-rate since pre-war days is probably brought about primarily by increased breast feeding, due partly to poverty and the giving of a small bonus for breast feeding and partly to the teaching of the welfare centres. In Munich, for instance, the amount of breast feeding at the beginning of the century was estimated at 25 per cent. and is now about 70 per cent., the death-rate in breast-fed babies between 1916 and 1919 was 103, and in artificially fed infants 219. The fact that the general infantile death-rate for the third quarter of 1923 showed no great rise is conclusive evidence that, up to that time, no severe privation had fallen on this section of the community.

Conclusions.

Throughout the investigation one of the greatest difficulties was that of separating the effects of previous periods of under-nourishment from malnutrition due to present conditions. As a group the infants appear to suffer least at the present time in Germany, and the weight at birth appears to be unaffected by the malnutrition of the mothers—a statement true also in Vienna throughout the post-war period. The group of children most affected are those from 2 to 5 years. This is well shown in the following table, indicating the general falling-off in weight during successive years of a group of children attending the welfare centres in Neukölln, a district of Berlin:—

Years.	Percentage of all children under weight.	Normal weight (per cent.).	Over weight (per cent.).
1–2	41	45	14
3–4	70	23	7
4–5	75	16	9
5–6	86·5	13	0·5

Generally speaking, boys appear to be less well-nourished and to suffer more in health than girls of the same age. The same held true in Austria during the time of privation, and is possibly to be attributed to the lesser activity of the girls. As compared with the British working-class standard, we considered a low standard of health more general, but the clothing of the children, except in two towns visited, was almost uniformly good. The footgear in many cases was, however, bad.

There is undoubtedly a definite deterioration in the physique of German children aged 2 to 14 since the beginning of the war. It is universally believed by German medical men that physique improved during the years 1921–22, and this is borne out by the figures available of the weights and heights of school-children, but it is probable that considerable sections of the child population are again deteriorating. More is at present being done to supplement the diet of school-children than of those under school age. There is no evidence of acute starvation of any extent among children in Germany, but a large section of those between 1 and 5 are suffering from an insufficient or ill-balanced diet.

In conclusion, we should like to express our indebtedness to the many members of the medical profession in Germany, and to those concerned in the care of children who freely put at our disposal all the information and facilities for which we asked, as without their constant help this investigation could not possibly have been carried out.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 29 cases were considered and £141 10s. voted to 28 applicants. The following is a summary of the three new cases relieved.

L.M.S.S.A., age 57, who practised in Essex. Since 1921 his ill-health required the constant attention of his wife who on this account had to give up a small business. Their total income now amounts to about 25s. per week. They live in a small bungalow which they purchased by money obtained on loan and a mortgage, the interest of which is £26 per annum and the rates £8 per annum. Voted £26 in 12 monthly instalments and a Special Grant of £5.

Daughter, age 66, of a surgeon who practised in Devon and died in 1870. Applicant's capital was expended in supporting a sister who was ill with consumption for four years before she died. She is now left with an annual income of £38, and gifts from friends amount to about £20, and she lives with a brother who finds her a shelter. Voted £10 in two instalments.

Widow, age 73, of F.R.C.P. Edin. who was an army doctor and later practised in Hampshire. Her husband died without making any provision. Applicant lost her income through a fraudulent trustee. Both her children are in financial difficulties and are unable to help in any way. In consequence of ill-health applicant is unable to earn. Voted £18 in 12 monthly instalments.

Subscriptions may be sent to the hon. treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., at 11, Chandos-street Cavendish-square, London, W. 1.

THE DIFFERENTIAL DIAGNOSIS AND THE PREVENTION OF SMALL-POX.

By A. F. CAMERON, M.D. Edin., D.P.H. Camb.,
MEDICAL SUPERINTENDENT OF RIVER HOSPITALS AND AMBULANCE SERVICE, METROPOLITAN ASYLUMS BOARD.

(*Concluded from p. 563.*)

The Prevention of Small-pox.

As a preface to this part of the subject I have to say that I am not concerned with the defence of the prophylactic value of vaccinia. The inoculation of vaccinia, if it is efficient and sufficiently recent, prevents small-pox. It is our only prophylactic.

During a recent investigation of an outbreak of the disease, I made a note of the following circumstances in connexion with a family of nine children. The mother stated that eight of her children had been attacked by the disease, and that none of the eight had been vaccinated. Every one of the eight showed evidence of a recent eruption which was consistent with the mother's statement, and with small-pox. The mother also stated that the ninth child had not been attacked by the disease, and that this child had been vaccinated. She was 11 years of age. She had no signs of having had an eruption and showed four vaccination scars, well pitted and of an area exceeding half an inch. I have quoted this case, not because the circumstances are in any way remarkable, but simply for the purpose of illustrating what is really meant by prevention of small-pox. If the other eight children had been in the same condition as the ninth the disease would not have appeared in this family. It would have been prevented. And so with other families, and so with the whole of our population.

We cannot entirely prevent the importation of the infection, nor, I believe, can we prevent the occurrence of a number of secondary cases among the people. But we can prepare ourselves to meet any importation of the disease, and we can so narrowly restrict the number of secondary cases that we shall be free from the constant menace of endemic small-pox and the ever-present risk of wide-spread epidemics of the disease. So for practical purposes one may say that the prevention of small-pox means the removal of the menace of small-pox, and the only means by which we can remove this menace is by increasing the immunity of the people. Prevention of small-pox therefore implies that the protective inoculation of vaccinia must anticipate the advent of the infection, and if we postpone the use of vaccination until the disease has appeared among the people, we are neglecting prevention and pretending to regard the presence of small-pox with all the social and commercial disturbances which accompany it, as an inevitable evil, although we are quite well aware that it is the most preventable of the infectious diseases.

Postponement of Use of Vaccinia till Small-pox has Appeared.

There are some among us who affirm their confidence in the prophylactic value of vaccinia, and yet do not hesitate to express the opinion, and to present the opinion as a guide for public policy, that we may safely neglect to employ the full power of prophylaxis, that the use of vaccinia may be safely postponed until the disease has appeared. The reason stated to underlie this opinion is that small-pox in the vaccinated but incompletely protected individual is apt to cause difficulty in diagnosis, and that missed cases therefore occur which spread the infection. I am not inclined to believe that this is a very frequent cause of missed cases. A neglect to exclude small-pox in course of diagnosis is certainly a common source of error. Even if difficulty arises because vaccinia has partly lost its efficacy through lapse of time or inefficient administration, that is no reason for advocating the less complete use of the prophylactic. It is a cogent reason for advocating the reinforcement of immunity. Recent experience in this country also shows that mild small-pox in the unvaccinated may give rise to similar difficulty.

The neglect of prophylaxis in this country and the result of that neglect are emphasised by Sir George Newman in his last report on the state of the public health. Under the heading The Present Situation, the Chief Medical Officer of the Ministry of Health states that the vaccination of infants has declined to 38 per cent., and goes on to say: "The administration of our vaccination laws may be open to criticism, and steps have been taken in the present year further to improve this administration. It is obvious that the vaccination laws themselves are in need of amendment."

For the purpose of debate I desire to make a few suggestions in the direction of strengthening the law and so enabling it more nearly to attain its object, the prevention of small-pox.

There is a great necessity for education of the people in the simple facts which underlie the production of immunity. The energy displayed in these days by sections of the public press in harrying small-pox nests is very admirable in intention, but is often misdirected on account of want of knowledge or appreciation of the true meaning and scope of protective inoculation. In an article dealing with the neglect of vaccination in a district where small-pox was rife the following sentence appeared: "The ordinary sane citizen, by the way, has a conscientious objection to being put in peril of a loathsome disease by the selfish obstinacy of a gang of fanatical fools." The "ordinary sane citizen" will protect himself. The prevention of small-pox is impeded by illogical thought and statement of this sort, and appeals founded on one's duty to one's neighbour, such as the advice that vaccination is necessary "not only for his own safety but for that of others," are not likely to be of much value. I would suggest that the public health authority should replace the board of guardians in executive control of small-pox prevention, and that it should be part of the duty of that authority to undertake the education of the people. The lines which this education should take and the methods of carrying it out will suggest themselves.

Compulsion in its Relation to Vaccinia and Small-pox.

The making of a law entails the prescription of penalties for its infringement. The removal of the penalty destroys the effective administration of the law. Within the last two decades, the removal of the penalty for the neglect of the law that infants must be vaccinated has gone far towards making vaccination law ineffective in this country. It is possible to re-enact the law. But would the re-enactment, taking into account the massive opposition which would be raised, justify itself by enabling us to attain our object, the prevention of small-pox? At the present time protection is afforded to 38 per cent. of children. There must be, and in fact there are, large sections of the community where the percentage of protection is much lower. One is not very hopeful of the result of an attempt to enforce the vaccination of infants in these districts. Let us consider the conditions which have to be met. Compulsion in any form is repugnant to us. To be tolerated it must make a valid appeal to reason. Having for four years fought against a system of government of which the basis and fabric were compulsion, it is not difficult for us to understand the attitude of the parent towards the compulsory vaccination of infants and children of tender age when we realise that he may never have heard of a case of small-pox or of fatal small-pox in his neighbourhood, and therefore has no experience of the results which may follow an attack. For example, suppose that a man were to receive at the present time a Government form instructing him that he is required to arrange for an efficient shelter for his children in the event of an air raid, that he will be penalised if he fails to do so within a stated period, and that he must supply documentary evidence that he has carried out the order. One can imagine his attitude. Compul-

sory vaccination of infants, in the absence of small-pox or of fatal or disfiguring small-pox, makes the same sort of appeal. It is a bureaucratic order which may lose its appeal to reason on account of existing conditions and of ignorance. Again, from the parent's point of view, the immediate and local effects of the inoculation are apt to be detrimental to the present well-being of the infant. In spite of our assurance that these effects are strictly transient, they appeal to the parental feeling and become especially undesirable when they cause disturbance of the father's or mother's rest. The appearance of signs of constitutional feebleness or disease is apt to coincide with, or to follow soon after, the transient effects of the inoculation. One meets at times with families in whom, for reasons such as these, the eldest child is the only one who has been protected.

Responsibility of the Parent.

To return to the illustration. Let us suppose that the father is informed that it is his duty to arrange for an efficient shelter for his children in the event of an air raid, because he is the responsible protector of his family, and that he will be penalised in the event of injury to any of his children in an air raid if he has neglected to take the precaution advised. Such an order would, I believe, appeal to his reason because he would recognise his responsibility. Prosecution now follows any gross neglect of children which causes them to suffer in their health or well-being, But it is necessary to prove the suffering and the neglect before a penalty is imposed. Why should the parent or guardian whose child contracts small-pox not be compelled to justify his action in a court of law if he has neglected to afford his child the only protection against the disease? or if he has neglected to take his precautions until he is too late to ensure complete protection? Why should he not be liable to serious indictment if neglect is proved and small-pox has been the direct or a contributory cause of his child's death? In a manifesto issued before the recent election, it is stated: "When Labour rules, it will take care that little children shall not needlessly die." The death of a child from small-pox is the most needless of deaths because the disease can certainly be prevented. I confess that I should like to see the penalty attached, not to the neglect of the vaccination of infants, but to the evil result which may follow that neglect. It is more logical and therefore easier to deal with actual than with potential crime.

Even if the attempt to reinstate the compulsory vaccination of infants was completely successful, this measure is not sufficient in itself to enable us to attain our object, the prevention of small-pox. The immunity produced by the operation gradually, and in most cases completely, disappears and must be reproduced. The most important potential carrier of small-pox is the adult and, I believe, particularly the male adult, who daily leaves and returns to the family circle. The majority of the mothers and infants and children under school age are naturally screened from attack by the restriction of movement associated with family life. The unprotected or partially protected father and older children who go to work bring the disease inside the screen. During the war a large proportion of these potential carriers of small-pox were rendered insusceptible by vaccination and revaccination. But we are now beginning to reap the fruits of our legislative destruction of the protection of children against small-pox, because as time goes on more and more of these unprotected children go out to work and join the ranks of potential carriers of the disease, and as a result small-pox appears to be gradually but surely re-establishing its former position in this country as an endemic disease, and a disease of childhood and early adult life.

Suggested Method of Ensuring Vaccination of Children.

I would suggest (*a*) that the first offer of protection should be made by the Registrar of Births and by domiciliary visit of the public vaccinator; (*b*) that examination and record of the vaccinal condition of the school-children should be part of the duty of the school medical service, and the information thus obtained made available for the use of the vaccination authority; (*c*) that protection should again be offered to the unprotected when the child enters school; (*d*) that protection in the case of unvaccinated children should be compulsory at the seventh year of age, and that exemption of this class should be granted only on production of a medical certificate that the child is physically unfit for inoculation; (*e*) that vaccination and revaccination of those previously protected should be enforced under penalty for refusal during the last year of school life under the same condition for exemption, and that insusceptibility at this period should not be certified until three unsuccessful attempts have been made to obtain a reaction.

If we genuinely desire to rid ourselves of the menace of small-pox, the necessity for compulsory protection at some period of life must be acknowledged. There are good reasons for removing compulsion from the period of infancy, and for using it at the later periods. Parental objections have lost much of their power when the child has reached the seventh year, and a rigid compulsion at the time when the youth is about to leave the security of family life, and if incompletely protected to become a potential carrier of small-pox, has an obvious preventive value. After school age compulsion should be applied in the case of all immigrants, and of all who have been in contact with the disease.

If our vaccination laws were so framed as to make a greater appeal to reason than they do now, and if protection were strictly enforced at the later ages, I do not say that small-pox would disappear from the country, but I believe that the percentage of children protected in infancy and early childhood would increase and that in the course of a few years we might expect to be free from the menace of endemic small-pox, and from the risk of widespread epidemic disease which now constantly threatens us.

Prevention of Spread of Disease is not Prevention of Disease.

The method employed in this country in dealing with small-pox is not prevention. It may be called the preventive treatment of small-pox. The method finds its legal sanction in the sections of the Public Health law which deal with infectious diseases. These sections are sometimes described as preventive, but they do not merit the title. They provide, it is true, for the efficient notification and isolation of cases of small-pox, for the destruction of infection, and to some extent for the supervision of those who have been in contact with the disease. But they become operative only after invasion by the disease has occurred, and their object is not the prevention of disease but only the prevention of the spread of disease. Our Public Health law has no dealings with prophylaxis, and the assumption which underlies its provisions is that these provisions are in themselves sufficient to attain their object—namely, the prevention of an epidemic of small-pox in a community which is completely unprotected against the disease. Until quite recent times our method of preventive treatment has met with considerable success in controlling the spread of the infection. The machinery of the method, notification, isolation, and disinfection, has been gradually tuned until it has apparently reached the greatest perfection of which it is capable. The measure of success which has been attained has brought with it the disadvantage that the observation and study of the disease have become more and more nearly the perquisite of a few members of our profession. Perhaps also as a result of the measure of success which has been attained and maintained until recent times, an unfortunate tendency seems to have arisen to express a complacent but unjustifiable satisfaction with the method, a tendency to regard vaccination and to speak of it as if it were only one means among others of preventing small-pox and of keeping the disease under effective control, and not really the only

means which is of any permanent value. It is, I believe, quite certain that our administrative method has attained its measure of success simply because it has enjoyed the essential but unobtrusive support of prophylactic vaccination, and if one may judge from present experience in several parts of the provinces the inability of the provisions of the Public Health law to control the movements of small-pox, when this essential support is undermined, is being very clearly demonstrated. One may assume that vaccination is being used in these districts to the fullest extent to which persuasion can carry it, but it has to be acknowledged that there is no provision in the existing law for the use of vaccinia in the control of an outbreak of small-pox. It is reasonable to suggest that the measure which is the only really effective means by which the law can attain its object, the prevention of epidemic small-pox, should receive legal sanction, and be embodied in the law in order that it shall be the duty of the public health authority to provide for and enforce vaccination on all who have been, in the opinion of the medical officer of health, in contact with the disease, and that a penalty shall fall on any authority or "contact" who knowingly evades the obligation or causes unnecessary delay in carrying it out.

However keenly we tune the machinery of our method, the method will at its best remain palliative. The neglect of prophylaxis and the freedom of choice given to the "contact" and to the vaccination authority, will maintain our risk of epidemic spread of the disease, and the enormous expenditure required in preparation to meet that risk, and so long as we continue to neglect prophylaxis, no improvement in administrative procedure can lighten the excessive responsibility now placed on the practitioner who must retain the supremely important duty of setting the machinery in motion. The personal question, "Can this patient's condition, at present obscure, be the result of the infection of small-pox?" has become under existing conditions in this country more vitally important than it has been in the past, and the failure to ask it, or delay in replying to it, is much more apt now than it has ever been in our time to give the disease the opportunity for which it is always ready.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The Ultimate Sequelæ of Infantile Cardiac Disease.

AT a recent meeting of the College of Viennese Doctors, which takes place weekly for the discussion of pathological problems, Docent Dr. Moll and Dr. Hecht discussed the late results of heart disease acquired in childhood. This chapter of pathology has hitherto received but scant attention from students. The Vienna children's clinic has instituted a regular control of cases that have been under treatment for a prolonged period, and these patients are invited to present themselves every other year for re-examination. Recently 42 former patients who had been treated for rheumatic endocarditis responded to the invitation. In 25 per cent. no trace of the affection was found, whilst 75 per cent. had signs of the disease. Cases which had left the hospital with symptoms of mitral incompetence now showed signs of mitral stenosis in addition. Furthermore, 21 cases of chorea minor or major, with concomitant valvular disease, came up for re-inspection, and in them the heart affection was still evident. Of nine cases of diphtheria, who suffered from cardiac trouble at the time of their dismissal from hospital, in three the heart proved normal on examination, whilst of six scarlet fever cases the heart was affected in two instances only, the other four being normal. All these control cases were seen seven to eight years after having left the clinic. In the opinion of the referees it is of importance in the after treatment to keep the patient in bed until the pulse-rate remains below 100, even after moderate exertion. As regards arrhythmia in children, in the majority of cases this symptom is due to respiratory influences unless an organic cause is present. The differential diagnosis of the former condition may be made from the fact that inspiration causes an increase of the heart beats, and expiration a decrease. Pathological arrhythmia is more frequent at the age of puberty. After infectious diseases, and also in cases of chronic constipation, one frequently finds in children a change in the pulse-rate, mostly of the type of extrasystole. A continuous arrhythmia (frequent in adults at the late stages of cardiac disease) is hardly ever encountered in children. As a rule all these cases clear up without delay. A diagnosis of organic cardiac disease in a child is not justified after a single examination, as other factors which emerge only after repeated examinations at varying intervals, such as accidental murmurs and variations of inspiration type, must be taken into consideration.

The Pathology of Goitre in Adolescents.

Dr. Gold, aided by Dr. Orator, read before the Medical Society of Vienna an instructive paper on the pathology of goitre in juveniles, based chiefly on anatomical investigations in 555 cases within the last two and a half years. Up to the seventeenth year the diffuse colloid goitre is more prevalent than the diffuse hypertrophic type. In older juveniles (19–21) the quiescent diffuse or the nodular type is more frequent. Girls reach the final stage of any particular type of goitre a few years earlier than boys, which seems to point to an endogenous factor (puberty?) in the genesis of the disease. Menstruation plays an important part in the rate and type of thyroid enlargement. Treatment by iodine seems to favour the formation of colloid goitre, as has been noted also in Eiselsberg's clinic. The anatomical structure of the juvenile goitre is a typical diffuse parenchymatous hypertrophy, with distinct formation of lobuli. Colloid material is present in small quantity only if no iodine treatment has been given. The iodine content of the examined thyroid gland is normal as a rule, the pharmacodynamic function is mostly normal or subnormal. Whilst in the juvenile goitre the number of follicles in the gland are increased and the epithelium is of one layer only, in the Basedow's (Graves's) disease the follicles are enlarged, but not increased in number, and the epithelium consists of several layers. Juvenile goitre does not represent a persistence of a previous stage of development, but is a compensatory hypertrophy due to previous hypofunction, and iodine treatment is justified. In cases of hypoplasia iodothyrin is required. Operation is advisable only when mechanical interference—e.g., pressure symptoms—becomes evident.

Venereal Diseases amongst Children under Welfare Care.

In a recent report of the Board of Guardians to the Municipal Council for Health, Prof. Tandler pointed out that venereal diseases were by no means rare in the children under the care of the Municipal Board for Juveniles. This office was organised some two or three years ago to look after the interests of children living in Vienna, from infancy up to the age of 18 years (apprentices and minors in industrial enterprises). School-children (aged 6 to 14), however, form the chief care of the board, including all orphans, waifs and strays, and other neglected children. In a central children's institute ("Central-Kinderheim") are housed all cases which cannot be looked after by friends or foster-parents, as well as weakly children not requiring hospital accommodation. Among the inmates of the institute no less than 150 have been found to be suffering from some form or another of venereal disease; acute or chronic gonorrhœal infection both in girls and boys is prevalent, but congenital syphilis is also fairly frequently found, whilst three cases of primary syphilis transmitted by careless friends or parents have occurred

only quite recently. A special pavilion, capable of accommodating 250 cases, will be devoted to the care of these children. This number will soon be reached, if the appropriate cases from the other institutes are also handed over to the venereal pavilion. It is intended to keep the children who are suffering from that intractable form of chronic gonorrhœal infection well known to all practitioners as a crux medicorum (and this condition is mainly found in girls of 3 to 12 years of age) separated from the other inmates for a prolonged period. A number of teachers and nurses will be employed exclusively in this pavilion, so that the children will not mix with the other inmates, whilst they can follow up the regular school teaching. Thus real isolation will be attained and spread of infection prevented.

Conflict between the Hospital Staff and the Nursing Staff in the Matter of Treating Abortion.

The controversy between the medical profession and the law over the right to induce abortion, which has been mentioned in a previous letter, has given rise to a noteworthy incident in one of our general hospitals. As a rule, the nursing staff in all public hospitals in Vienna consists of Catholic nuns. In the last few weeks the nuns doing service in the surgical department of this hospital refused to give assistance at any operations in the nature of abortion. It must be pointed out that combined surgical and gynæcological wards are common in our outlying hospitals. The nuns in this case obeyed orders given by their matron, herself a Catholic nun, who no doubt acted under instruction from high quarters as a protest against modern ideas of eugenics and against restriction of birth from considerations of economics and morals. When the nuns refused to do their duty at gynæcological operations of this type, the medical staff organised a subsidiary service, whilst a complaint was lodged with the Ministry for Public Health as superintending authority against the nursing staff. A speedy remedy of the grievance was expected; instead, the Ministry decided that in future gynæcological surgery should not form part of the regular work of the surgical department of this particular hospital! Naturally the medical staff will not accept this ruling. Energetic measures are in preparation, and the coöperation of the profession will be obtained by the aid of the Union of Economic Organisation in order to bring about such a solution as will be acceptable to the medical staff of the hospital.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Glasgow Royal Mental Hospital.

THE annual report of the physician-superintendent of the Glasgow Royal Mental Hospital—an advance copy of which reaches us through the courtesy of Dr. D. K. Henderson—contains many statements of interest. In the first place, the statistics of admissions and discharges are noteworthy. Of 120 discharges, 39 recovered, 27 were greatly relieved, and 13 were not improved. A complete recovery-rate of 32·5 per cent., as Dr. Henderson points out, is a satisfactory answer to the firmly rooted belief that "no one is ever likely to get better in a mental hospital." Of 120 admissions, 116 were private cases, and of these 53 were admitted as voluntary cases. Dr. Henderson stresses the great importance to be laid upon the recognition by the patient that he is mentally ill, and his subsequent coöperation in treatment, whether this be in an institution or not. That treatment can be successfully carried out without recourse to the mental hospital is reflected in the statement that in a little over a year, while 80 patients applied for advice at the out-patient psychiatric department of the Western Infirmary—where Dr. Henderson is in charge—in only two cases was it necessary to advise treatment in an institution. Public recognition of the value of prophylactic measures of this nature must show itself in the course of time both in the admission and recovery-rates recorded by institutions in centres where they are practised. A complete consulting staff has been appointed to the Hospital, and it is hoped that with their aid the interrelation between physical and mental illness may be more thoroughly investigated. During the year observations have been made upon the blood-sugar content, particularly in states of anxiety and depression; an attempt has been made to treat possible intestinal infection with bacillus acidophilus milk; and histological studies of cases of dementia præcox have also been carried out.

Occupational Therapy in Early Mental Disorder.—In recent years, the revival of occupational therapy as an aid to the treatment of early mental disorder has attracted a good deal of attention; and a considerable part of Dr. Henderson's report is devoted to this aspect of institutional life. In such a hospital as the Glasgow Royal Mental Hospital the majority of the patients are drawn from the professional and business classes. From both a physical and psychical point of view routine work is unsuitable for these patients. What is required is a task, suitably interesting and æsthetic for people of culture, and, moreover, so planned that it is capable of fulfilment by the particular patient. The confidence engendered and restored by a course of such occupational therapy is often of striking service in enabling the patient to make the mental readjustment necessary for his cure. Bearing this in mind, the Glasgow Royal Mental Hospital is to be congratulated on being "the first mental hospital in the British Isles to appoint a full-time occupational teacher, and to provide a separate occupational pavilion for the development of this type of therapy." Dr. Henderson concludes by making an appeal for a "well-educated, intelligent, refined type of girl" to take up mental nursing, which, as he points out, is a far more specialised calling than is generally supposed.

The Morison Lectures.

In his third lecture Dr. John Thomson dealt with the treatment of the mentally defective infant. The mainstay of this treatment is training, the burden of which falls on the mother, and it is the part of the medical man to instruct her. Dr. Thomson considers that it is usually best to reveal as little as possible to her of the true state of affairs, in view of the fact that many of these children die early from complications. The mother may in this way be spared much unnecessary distress. All that is usually required is to tell her that the baby is unable to do certain things that other babies can, and that with time and careful training he may be much improved. Constant repetition is necessary, and for this purpose the services of a tactful and sympathetic visitor are invaluable. To begin with, the mother must notice what things her baby is not doing as the normal baby should, and try to teach him to do them better one by one. He should be especially encouraged in anything he finds a little difficult, as any success he has will give him special pleasure, and so lead to confidence and encourage to further effort. As he grows older the mother must be careful never to do anything for him that he has learnt to do himself. She must be warned to watch for and check any bad habits the baby may develop, his attention, if possible, being drawn to something else. If he is slow in learning to speak, he should be constantly spoken to, even though he appears to be unheeding. She must attempt to develop character by increasing his self-control and independence. Affection for human beings or even animals and dolls is efficacious and should be encouraged. The emptying of the bladder and bowel in mentally defective children, as in young babies, generally takes place at regular intervals. The mother must try to find out the length of these intervals in her child's case, and lift him at the right times, so as to form a good habit.

The effect of this on character and happiness is very striking. Chewing of solid food may have to be taught. Open air is often beneficial in cases of constant, apparently causeless crying. In spastic diplegia special exercise should be used to help and encourage the child to gain more control over the stiff limbs. Passive and active movement should be employed. As the child gains more control simple games should be devised to induce him to use his limbs more freely. Dr. Thomson regards surgical interference as of occasional value in these cases.

Measles in Scotland.

The Scottish Board of Health has issued a circular to the local authorities announcing that, with the consent of the Government, a sum of £10,000 has been added to the maternity and child welfare grant, to be set aside for the treatment and control of measles. Recognising the very high death-rate from measles in children under 5 years—and a considerable proportion of these deaths occurs in infants under 1 year—while after the age of 5 years measles becomes much less dangerous, the Board considers that the problem is, perhaps, not so much the prevention of the occurrence of measles in the child as the postponement of it to the later years of childhood. Local authorities are invited to submit proposals for the further provision against measles, which might run on the following broad lines set out by the Board: (*a*) Notification of the disease; (*b*) appointment of a special ad hoc staff of visiting nurses for infectious diseases; (*c*) increased hospital facilities; (*d*) an increased service of health visitors. The scope of these preventive measures may also be extended to include whooping-cough.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Dangers of Swimming Pools.

MANY cases of spirochætosis hæmorrhagica have recently been reported in individuals habitually frequenting the swimming pools which have of recent times been established in the poorer quarters of Paris. No other source of contamination having been discovered, it is thought that the infection must have arisen through the insanitary condition of these pools, and the Société de Médecine de Paris has passed the following resolution: "That this society, prompted by the recent outbreak of spirochætosis hæmorrhagica contracted in a Parisian swimming pool, coming after numerous cases reported of conjunctivitis, suggests that swimming pools of the city of Paris should be better supervised; that their water should be changed more often, and, above all, that bathers should not be allowed to go into the water except after thorough washing of the whole body with soap and tepid water."

Spread of Malta Fever by Goats.

Every Parisian remembers from childhood the pleasant sight of the itinerant goatherds, in the quieter quarters of the city, leading their little flocks of five to ten goats to the sound of a rustic flute. These were the vendors of goats' milk, and they brought something of the Mediterranean sunshine into the streets of Paris. A customer would bring a bowl, which the flute-player would fill with warm milk drawn there and then from one of his herd. Unfortunately, it has been found that this milk was dangerous. Several cases of Malta fever (*Micrococcus melitensis*) were notified in Paris, and investigation showed that children were infected by the milk of these itinerant vendors. In consequence, an order has been issued prohibiting the sale of milk from such sources in the public streets, and the Council of Public Health of the Department of the Seine, under the presidency of Prof. H. Vincent, has enacted the following measures: (1) veterinary inspection of goats; (2) control of itinerant goats'-milk vendors in the Department of the Seine. Goats which come from contaminated districts must not be allowed on the streets. Only thus can protection be ensured from a disease whose spread would be a great danger in the north of France.

An Epidemic of Donors.

A curious epidemic of people desiring to give blood for transfusion has been reported by two doctors from l'Hôpital Lariboisière to the Academy of Medicine. Three people came to the hospital in one week offering their blood for various purposes. The first was a young man of 22 who asked that his blood might be used for transfusion into that of any patient seriously ill. Next, a woman aged 35 desired to make an important communication to the chief medical officer, the communication being the expression of a wish to give her entire blood to a sick person in order that she might be of some use before dying. The third applicant was a young man who found his way to a ward and declared to the nterne who received him his desire to lend himself for the performance of some experiment for the advance of medical science which would involve bleeding him to death. The explanation why in the Lariboisière quarter alone so many people should desire to sacrifice themselves in this special way is explained by the fact that in a cinema near the hospital a film has been shown wherein the heroine offered transfusion of her blood in dramatic circumstances.

ROYAL MEDICAL BENEVOLENT FUND GUILD.

THE fourteenth annual general meeting was held at 11, Chandos-street, Cavendish-square, London, W., on March 12th, Lady (Rose) Bradford presiding.

Lady Fripp, chairman of the Council, read the report of the Council for 1923, which recorded increased support of the Guild by members of the profession and their friends. The festival dinner held in February, 1923, gave a great impetus to the work and its effects have been far-reaching. The sum directly realised was £1336 and, moreover, as a result of the scholarship scheme advocated by Sir Douglas Hogg in his speech, two new scholarships have been founded, one by the Manchester branch, and the other by Mr. Noel Wills, in memory of his mother. In each case the sum given was £250, which sum invested yields £30 annually for ten years. The St. Pancras branch had been resuscitated, and a North London section of the Guild had been inaugurated. Bournemouth had trebled its subscription, and Cardiff and Glasgow had sent most encouraging statements of increased contributions. Edinburgh, Peebleshire, Hampstead, Kennington, and Westminster had also made extra efforts. The Ladies' Medical Golfing Society competition brought in over £150, and the amount had been invested to found a scholarship of £30 for five years.

Mrs. Scharlieb, M.D., hon. treasurer, submitted the financial statement. The annual subscriptions in 1923 amounted to £1224, an increase of £120. Donations, under which heading were included the results of special efforts made on behalf of education, amounted to £3080, being £1925 more than in 1922. The total receipts for the year amounted to £4704; of this sum £900 had been devoted to the purchase of scholarship annuities; £2402 had been spent directly upon the Guild beneficiaries (£872 being for education); £1000 had been invested in War Loan, and the balance brought forward, after meeting general expenses, was £391.

Mrs. Arthur Ormond read the report of the Visiting and Case Committee. During 1923 the Committee had apportioned £766 in monthly grants, the recipients numbering 52. This was an increase of £138 over the amount spent in 1922, and more than £300 above that spent in 1921. Acute poverty, old

age, illness, and other causes resulting in inability to work formed the main reason for these grants. In addition, 54 applicants received special gifts of money during the year amounting to £312 in all, for sudden emergencies, such as sanatorium fees, special medical treatment, maintenance while waiting for a post, removal expenses, remedial exercises, fares, outfits, arrears of rent, and so forth. Spectacles had been supplied to three beneficiaries, and eight had had dental costs paid for them. £65 had been distributed in coal grants amongst 63 applicants. Holidays had been secured for 18 persons, and this was recognised increasingly as an extremely valuable part of the Guild's work. The Committee thanked those who had sent Surgical Aid letters and appealed earnestly for more of these, also for Royal United Kingdom Beneficent Association votes. The educational branch was a source both of anxiety and pride. The responsibilities of this work were shouldered almost entirely by the Guild, since all appeals made to the Royal Medical Benevolent Fund are referred to the Guild. The anxiety arose from the increasing number of applications for assistance as this enterprise of the Guild became more generally known. £872 had been spent on education and training during 1923, against about £700 in the previous year. Training had been given for most varied careers, for example, secretarial work, partial fees for a lady dentist, fashion artist, teacher of physical exercises, cookery, &c., and maintenance was paid in several cases where no money was available for food and housing during training. Mrs. Ormond described in detail the pitiable condition of various recipients of help from the Guild, and made it clear that the constructive policy of the Guild was to assist to earn, to educate to earn, and to induce self-reliance. Herein lay the explanation of the widening of its self-imposed responsibilities in undertaking educational and training schemes. It was satisfactory to note that there had been no instances during the past year of any beneficiary losing through his own fault a berth obtained for him. School reports and reports of careers subsequent to school life had been gratifying. It must not, however, be forgotten that the work could only be carried on if the medical profession maintained the inflow of money.

In the absence of Miss Swinford Edwards, the report of the Father Christmas branch was read by Lady Fripp, who also read a report of the Clothes Committee.

Lady Lewis moved, and Mrs. Laming Evans seconded, the re-election of Lady Bradford as president, Lady Fripp as chairman of the Council, and Mrs. Scharlieb as hon. treasurer. Mrs. Woodwark moved, and Miss Jenkyn Brown seconded, the resolution that Mrs. Barrett, Lady Lewis, and Mrs. Liveing be elected members of the General Purposes Committee. These motions were agreed to, and a vote of thanks to the President and Council, proposed by Mrs. Wilfred Harris, was carried with acclamation.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. R. B. Ainsworth to be Lt.-Col.

Capt. J. H. C. Walker to be temp. Maj. whilst empld. as a Dep. Asst. Dir. of Pathology.

MILITIA.

Capt. W. A. Miller to be Maj.

TERRITORIAL ARMY.

Lt. R. Morris (late Lan. Fus.) to be Lt. for service with Leys School Contingent, Jun. Div., O.T.C.

Lt. P. Mumford to be Lt.

General Hospitals: Lt.-Col. A. L. Flemming, having attained the age limit, is ret., and retains the rank of Lt.-Col.

Capt. A. C. Court to be Maj. (Prov.).

Capt. C. B. Moss-Blundell having attained the age limit is retd. and retains the rank of Capt.

Capt. A. N. Smith (late R.A.M.C., S.R.) to be Capt.

Correspondence.

"Audi alteram partem."

THE RISKS OF CERTIFYING IN LUNACY: INDEMNITY INSURANCE.

To the Editor of THE LANCET.

SIR,—With reference to the leading article on the case of Harnett *v.* Bond and Adam, published in your issue of March 8th, there can be no doubt as to the serious effect the decision of the courts in this case will have on the minds of all members of the medical profession—not only on those members of that profession who specialise in mental cases. The decision, however, only serves to emphasise the very grave risks to which all persons who are engaged in a professional capacity are daily subjected in carrying out their duties towards their patients or clients, notwithstanding how skilfully or carefully such duties may be exercised. The decision also serves to emphasise very strongly the fact that doctors, surgeons, and other medical practitioners should seriously consider the advisability of protecting themselves individually, by means of insurance, against possible claims for damages, in the same way as other classes of professional men have deemed it essential to do for a considerable time past.

Accountants, solicitors, directors of public companies, and other classes of professional men consider it money well spent to arrange insurance indemnities so that they may carry on their profession untrammelled by the ever-present risk of finding themselves ruined financially from the action of some ungrateful or spiteful client; for it must not be forgotten that, even though an action for damages may fail, the cost of defending such an action is heavy and often beyond the means of the unfortunate victim, the professional man.

This subject of professional indemnity insurance is one which has not received, hitherto, the publicity and attention which it deserves. The facilities which are available to accountants, solicitors, and others are equally available to members of the medical profession—at a very low cost—and with the remedy in their own hands, it would seem that the medical profession have not much need to fear the effect of the decision in the Harnett case.

We are, Sir, yours faithfully,

SANDERSON AND CO.,
Insurance Brokers.

91–93, Bishopsgate, London, E.C., March 7th, 1924.

*** The measure of the protection offered to medical men by their own admirable defence societies is indicated in their annual reports. The extent of the cover afforded to members of the Medical Defence Union against damages and costs of the other side in the event of an adverse verdict is now £3000, in any case which is undertaken on behalf of the member by the Council of the Union, and it must not be forgotten that a member of the Union is provided with his legal defence entirely free of cost to himself in addition to the indemnity insurance. The London and Counties Medical Protection Society undertakes to grant a similar indemnity to its members. In view of recent events it is probable that the Councils of the two Societies will consider carefully the question of extending the benefits of their present indemnity insurance. No doubt it is possible to insure against any risk by paying the necessary premium, but it seems unlikely that any insurance brokers could afford to insure individual members of the profession to the same extent as the cover provided by the defence unions, except upon a greatly enhanced premium. In giving protection at the rate of £1 to cover an insurance of £3000, the defence societies retain the power to refuse to indemnify at the discretion of the Council. Without this power of refusal the insuring society or company might be ruined by

insuring some disreputable individual. On the other hand, the Council of a medical protection society, if it did not do justice to a member, could be turned out forthwith. Since an insurance company is not subject to any such discretion the precise conditions have to be set forth minutely when the insurance might fail at a critical point.—ED. L.

CERTIFICATES OF INSANITY.

To the Editor of THE LANCET.

SIR,—It is not quite clear what Dr. H. Rayner[1] desires; he appears to object to the responsibility attaching to certification, but could this be diminished or could the duty be performed by non-medical citizens? The risk indeed is small to a man who appreciates what he is doing, and who acts with commensurate care, while the responsibility for ordering detention actually does rest with the legal authorities. All that is required of the medical "witness" is definite, verified, or referenced evidence sufficient to enable this authority to form his own opinion. If only vague, "scrappy," technical *evidence* is offered, this will throw a greater moral onus upon the medical *opinion* "that the patient should be detained."

The very gravity of the charges that have to be made against a medical man for wrongly certifying (in order to constitute an actionable complaint) shows how well the profession is protected from frivolous recriminations. If the practitioner desires further security, he need not certify; or he could safeguard himself to some extent by refusing to accept a fee. Further legal immunity—security for the profession—could probably only be obtained at the expense of public security (from unconscientious certification), and even if we desired and could obtain this it would only aggravate the public suspicion, which is our real grievance.

It is quite true that the community demands full protection from insane conduct and then "salves its conscience" by reviling and penalising its obedient protectors, but psychiatry is not the only sufferer from this. The most it justifies us in demanding is a more definite and explicit statement of the principles upon which the community sanctions interference with personal liberty. It cannot be denied, moreover, that our own advocacy of compulsory detention for *curative purposes* as distinct from *security* has added to the prevailing uncertainty as to the grounds upon which detention is recommended and sanctioned.

Dr. Rayner's contention that "a non-official general practitioner is not the servant of the legislature, and should therefore not be required to take any responsible part in carrying out its objects," appears to me inadmissible and dangerous doctrine, as also does his demand that medical certificates of insanity should be secret and "privileged" documents. These form an essential part of the procedure for restricting the liberty of a fellow-citizen, and must stand public scrutiny. British law does not act on secret and *non-responsible* evidence.

Corporate action by the profession on the lines he advocates, and at the present moment (with a Government inquiry pending) appears to me very undesirable, especially action that appears designed to "force the hand" of the legislature. The only real and satisfactory security we can have is the confidence of the public. Vindictive and unreasonable action on their part is symptomatic of suspicion and a feeling that safeguards and supervision are insufficient. We have nothing to lose by any measures of security it may please to take; we have everything to gain by an overhauling of the Lunacy Law with which the profession has never been content. This overhaul has been promised, and surely our business is rather to prepare our case than to prejudice it by partisan action.

I am, Sir, yours faithfully,

Perth, March 15th, 1924. I. D. SUTTIE, M.B.

[1] THE LANCET, March 15th, p. 570.

To the Editor of THE LANCET.

SIR,—Dr. Rayner's suggestion for the protection of medical practitioners through the wiping out of every trace of the evidence given by them for committal to an asylum would, I fear, be likely to lead to a reaction in the direction of providing more safeguards for the individual concerned. It would also incidentally abolish Section 82 of the Lunacy Act.

The question of a doctor's liability in the matter of signing a certificate did not arise in the recent action of Harnett *v.* Bond and Adam. Certifying doctors are at the present moment amply protected by reason of the fact that in the eye of the law it is the reception order signed by the judicial authority, and not the medical certificate, which is the cause of the alleged lunatic's committal. The certifying doctor escapes liability on the ground that he is only a witness tendering evidence. In common with all other witnesses, the reliability of the doctor's evidence ought in fairness to be tested through cross-examination by the solicitor or friend of the alleged lunatic in the presence of the magistrate and of the individual himself. Should the latter desire it, the whole proceedings could be conducted in privacy. Doctors need not consequently be in any dread as to liability for damages arising out of bona fide certification, while their sworn evidence from the witness-box will be regarded as strictly privileged.

I am, Sir, yours faithfully,

S. E. WHITE, M.B., B.Sc.

Tower Hill, E., March 16th, 1924.

To the Editor of THE LANCET.

SIR,—I have read Dr. H. Rayner's letter in your issue of March 15th, in reply to which I think the point he raises is covered by the last paragraph of Section 330, Subsection 1, of the Lunacy Act, 1890, which reads as follows: "He (the doctor signing the medical certificate) shall not be liable to any civil or criminal proceedings whether on the ground of want of jurisdiction or any other ground *if such person has acted in good faith and with reasonable care.*"

I am, Sir, yours faithfully,

STANLEY A. GILL, M.D., &c.

Formby, Lancs, March 17th, 1924.

HARNETT *v.* BOND AND ADAM.

To the Editor of THE LANCET.

SIR,—In your leading article with reference to this case in your issue of March 8th, 1924, I note with satisfaction that you express yourself as "amazed and horrified" that the jury should have found that Dr. Bond was aware of the plaintiff's sanity at the time when he was taking measures to return him to Malling House, and in addition to which I believe he stated in his evidence that he considered him to be of unsound mind. You also draw attention to the fact that Justice Lush expressed himself surprised on learning that the patient is not personally made aware of the grounds of his detention, and, if I remember rightly, conveyed the impression that he considered the patient should be presented with a copy of his certificate. Personally, I have always treated these certificates as confidential documents, and I should be interested to know whether this is not the way that they are looked upon by every Medical Superintendent, and also whether this is not the attitude the Medical Profession would expect us to adopt?

I am, Sir, yours faithfully,

RICHARD EAGER, O.B.E., M.D.,
Medical Superintendent, Devon Mental Hospital, Exminster.

March 12th, 1924.

*** To a question asked in the House of Commons last week "Whether, in view of the verdict in Harnett *v.* Bond and Adam, the Minister of Health proposed to suspend Dr. Bond from acting as a Lunacy Commissioner pending the decision of the Court of Appeal," Mr. Wheatley replied in the negative. Mr. Wheatley called attention to the fact that a

discussion could not be entered into upon a case which is still *sub judice*, but he went on to say: "I would draw attention to the fact that Mr. Justice Lush stated that he agreed that there was no evidence of any dishonesty or *mala fides* on the part of Dr. Bond. In view of this fact, and of Dr. Bond's long and distinguished record of public service and his eminent position in the scientific world, I see no reason to take the action suggested." The answer was not given orally, which is to be regretted, as possibly supplementary questions would have made certain points clearer. With the learned judge's expression in court, after the verdict, we cordially agree.—ED. L.

MEMORIAL TO PROF. O'SULLIVAN.

To the Editor of THE LANCET.

SIR,—Two meetings of the late Prof. A. O'Sullivan's friends have been held in Trinity College, at which it was resolved to found a memorial to him in connexion with the Medical School in Trinity College, where he held for so long the chair of pathology. Any of your readers who may wish to take part in the project are asked to write to either of the undersigned, who will supply further information.

We are, Sir, yours faithfully,

E. J. GWYNN, } Honorary
JOSEPH W. BIGGER, } Secretaries.

Trinity College, Dublin, March 15th, 1924.

B. PYOCYANEUS INFECTION.

To the Editor of THE LANCET.

SIR,—The case of *B. pyocyaneus* infection reported by Dr. H. Ronald Carter in THE LANCET of March 1st is very interesting. Now and then one discovers this organism in various parts of the body, usually in association with other bacteria, and the question of vaccine treatment is raised. My object in writing this note is to draw attention to a method of treatment which Dr. Carter has not mentioned, and which I was taught some years ago—i.e., irrigation with 1/500 or 1/1000 biniodide of mercury. Since that time I have invariably advocated this method and it seems to work very well indeed. When there is an open wound or channel and irrigation can be carried out freely most of the cases have cleared up in a week or two. I have never used a vaccine but have always held one in reserve, and am grateful for the warning as to the severity of the reaction which may take place unless the dose given is very small. As Dr. Carter points out, the bacteriologist cannot always tell what the minimum dose in a particular case should be, and when a violent reaction does occur it is not easy to persuade the patient to continue with the treatment. An experience of mine has some bearing on this point. A short time ago the initial dose of an autogenous vaccine which I made for "colds" was followed by a general urticarial rash within 24 hours, and the patient was greatly alarmed. I felt sure it was not due to the character of the vaccine, and asked for its return with a view to investigation. I first injected some under my own skin and then inoculated some into various media. My skin showed a slight reaction —redness and swelling—and the tubes remained sterile. My relief can be imagined. I take it the urticaria was due either to an idiosyncrasy on the part of the patient, anaphylactic phenomenon, or to a coincidence. The patient has since received several doses of the same vaccine without any untoward symptoms.—I am, Sir, yours faithfully.

ERNEST H. SHAW.

Royal Northern Hospital, March 12th, 1924.

DONATIONS AND BEQUESTS.—By will the late Lieut.-Colonel John Ritchie, of Mossley Hill, Liverpool, left £500 to the Royal Southern Hospital, Liverpool, and £250 to the Liverpool Royal Infirmary; the Children's Infirmary, Liverpool; the David Lewis Northern Hospital, Liverpool; the Bootle Borough Hospital; and the Liverpool St. Paul's Eye and Ear Infirmary.

Obituary.

ROBERT ALEXANDER BICKERSTETH, F.R.C.S. ENG.

Mr. R. A. Bickersteth, honorary consulting surgeon to the Royal Infirmary, Liverpool, died at Bournemouth on March 6th in his sixty-second year.

A son of the late Mr. E. R. Bickersteth, F.R.C.S., Robert Bickersteth was educated at Eton and Trinity College, Cambridge, gaining the Natural Science Tripos in 1884 and his M.A. in 1887. He obtained his surgical experience at St. Bartholomew's Hospital, graduating M.B., Ch.B. in 1891, and in the same year he became a Fellow of the Royal College of Surgeons. He was appointed honorary surgeon at the Royal Infirmary, Liverpool, some 30 years ago, and later became lecturer and examiner in clinical surgery in the University of Liverpool. As a clinical teacher he appealed to the student by the practical usefulness of what he had to offer them; he laid stress on the importance of painstaking observation and on the maxim that more errors are due to want of care than to want of knowledge. When he relinquished the position of honorary surgeon at the infirmary in 1921, the committee of that institution elected him honorary consulting surgeon in recognition of the services which he and his family had rendered to the infirmary for three generations. He was a member of the Association Internationale d'Urologie and a corresponding member of the Association Française d'Urologie. His publications on urinary surgery, which appeared in THE LANCET and elsewhere, were much in advance of his time. Twenty years ago he perfected and described an intravesical arrangement for drawing off urine from either ureter separately, and he went on to catheterise the ureters and to deduce from the results the conservative surgery of the renal pelvis. His knowledge of morbid anatomy was sound, and he was apt to see with the naked eye what others required the microscope to discern.

We have received the following personal appreciation from "J. T. M.":—

"Of the late Mr. R. A. Bickersteth it is difficult to write in such a way as adequately to convey a picture of that gentle, kindly personality that won him so many friends. He was one of those men, gifted with a charm that could not fail to draw friendship, who through the shyness of his demeanour often left his quiet humour and his sense of the deep things of life unsuspected. A man of the highest ideals in his profession, he was a good friend to the Liverpool Medical Institution, to which he gave his library, comprising many rare and valuable volumes, on his retirement. Mr. Bickersteth took more than a passing interest in astronomy, and photography also claimed his attention. His great hobby, however, was shooting, and only rarely did a season pass without a visit to Scotland. During the war he served at home and for more than a year in No. 57 General Hospital in France, and there is no doubt that it was during that time that his health began to fail. It will be long before his fine presence and his kindly heart will be forgotten."

On March 5th a memorial service was held in the Chapel of the Royal Infirmary, where Mr. Bickersteth had spent many years of devoted service. The service was conducted by the Rev. Mr. Macdonald, chaplain to the hospital, and there was a large attendance of friends. Mr. Bickersteth is survived by a widow and several sons and daughters.

DONALD WILLIAM CHARLES HOOD, C.V.O., M.D. CAMB., F.R.C.P. LOND.

WE regret to announce the death of Dr. Donald Hood, consulting physician to the West London Hospital, which occurred on March 15th at his house in St. John's Wood, where he had gone to reside on retirement.

Donald William Charles Hood was born in 1847 at Market Lavington, the eldest son of Sir Charles

Hood a Lord Chancellor's Visitor in Lunacy. He was educated at Harrow and Gonville and Caius College, Cambridge, completing his medical education at Guy's Hospital. He graduated in medicine at Cambridge in 1871, proceeding eight years later to the M.D. degree and taking the Membership of the Royal College of Physicians of London in the same year, being later elected Fellow.

After holding appointments at Guy's Hospital, he was appointed assistant physician to the West London Hospital, and obtained excellent early introduction to private practice by close professional relations with Sir William Gull. He proved himself in public and private capacity a very able physician. He did excellent work in the early "nineties" in connexion with the treatment of rheumatism, publishing statistics with reference to the use of salicylates in acute cases which were recognised as of real practical value. He wrote critically also on the diagnosis and treatment of typhoid fever and on acute pneumonia, while a long line of residents at the West London Hospital could testify to his merits as a hospital physician and a clinical teacher. His professional position, although he was not on the staff of any teaching hospital, was recognised by his appointment as examining physician to the Foreign Office, and as an examiner of medicine in the University of Cambridge. He was decorated after the Boer War for services rendered in connexion with two great funds instituted for the relief of wounded and sick officers during that war, while he was also both a governor of Bethlem and Bridewell Royal Hospitals and a member of the board of management of Earlswood.

Dr. Hood married Alice, daughter of John Wickham Flower, by whom he had one son and three daughters.

THOMAS BRITTIN ARCHER, M.R.C.S. ENG.

THE late Mr. T. B. Archer, who died recently of angina pectoris in his seventy-ninth year, was the youngest child of Mr. Goodwyn Archer, of Ely, Cambridgeshire. Born in 1846, he was educated at the King's School in Ely and afterwards at the Grammar School at Ipswich. In 1865 he was apprenticed to Dr. Richard Jones, of Woodbridge, Suffolk, and completed his medical studies at St. Bartholomew's Hospital, obtaining the qualification of M.R.C.S. When the first ophthalmic ward of St. Bartholomew's Hospital was opened, Mr. Archer was appointed ophthalmic house surgeon in November, 1870, and served for a year. Subsequently he visited in rotation the principal ophthalmic hospitals in Brussels, Berlin, and Vienna for a period of nearly three years. On his return in 1873 he was appointed clinical assistant to the Central London Ophthalmic Hospital and the Royal London Ophthalmic Hospital, and became surgeon to the former hospital in the same year. He rose to the senior surgeoncy in 1879, and from that time as chairman of the medical committee did all in his power to increase the efficiency of the hospital both as regards its structure and personnel.

Retiring at the age limit of 65 in 1911 he became chairman of the hospital at the most critical period of its history when its funds were at low ebb and money had to be obtained to build a new institution, and it may be said that to his services the new hospital owes its existence.

On the outbreak of war he once more became an active member of the staff, helping daily to replace those members of the staff who had been called up on active service. In appreciation of his work the committee of management named one of the wards in the new hospital the "Archer Ward." In 1921 he resigned the chairmanship of the hospital and retired into private life. He was fond of music and painting, and in his youth was an expert with both rod and gun. Under a somewhat critical exterior he hid a generous, straightforward nature which endeared him to those who knew him well.

GEORGE PALMERSTON NEWBOLT, F.R.C.S. ENG.

THE sudden death of Mr. G. P. Newbolt, lecturer on clinical surgery at the University of Liverpool, on March 9th, in his sixty-second year, came as a great shock to the medical community in Liverpool, where Mr. Newbolt filled an important and an honoured place. He received his medical education at St. Bartholomew's Hospital, London, and at Durham University, graduating M.B. Durh. in 1884. The following year he obtained the M.R.C.S. Eng., followed in 1888 by the Fellowship. Later, in 1896, he became a Heath scholar of Durham University, where he worked for some time as assistant demonstrator in anatomy. After graduation he continued his training as a house surgeon at St. Bartholomew's, and on leaving London was appointed surgeon to a section of the Manchester Ship Canal. Here he came in touch with Sir Robert Jones, with whom he formed a life-long friendship. On the completion of work on the canal Mr. Newbolt became surgeon to the Liverpool Stanley Hospital till 1897, when he was elected to the staff of the Royal Southern Hospital, ultimately reaching the position of senior surgeon and dean on the retirement of Sir Robert Jones. Mr. Newbolt also held the appointment of honorary consulting surgeon to the Clerical Union, North-Western District, and of honorary surgeon to the Leasowe Hospital for Children. He published several interesting monographs on various aspects of surgery in the *Liverpool Medical Journal* and elsewhere.

During the war Mr. Newbolt did untiring work in connexion with the officers' hospital at Croxteth Hall and the Myrtle-street Auxiliary Hospital. He was at one time chairman of the Medical Faculty of the University, and recently was elected president of the Liverpool Medical Institution. Superficially he was not one to attract friendship, but his real worth became apparent on further acquaintance, and those who knew him best respected him most. He leaves a widow, a son, and three daughters.

HENRY HAMMOND SMITH, M.R.C.S. ENG.

Dr. H. H. Smith, surgeon to the Corbett Hospital, Stourbridge, died on March 4th at his home in Kensington at the age of 73. Born in 1851, he received his medical training at Middlesex Hospital, qualifying M.R.C.S. in 1872 and L.R.C.P. two years later. His work as a general practitioner gave him a first-hand knowledge of factory work and factory conditions, and when in 1901 a Royal Commission on Arsenical Poisoning was established, Dr. Smith's services were engaged to investigate the liability of articles of food and drink to be contaminated by arsenic. His inquiry was detailed and exhaustive and the results of his work are recorded in an appendix to the report of the Commission, which is still worth reading. He also carried out investigations on behalf of the Royal Commission on Tuberculosis during the years 1905 to 1907, when he did valuable work in connexion with swine tuberculosis and also in obtaining material for the Commission's inquiry into lupus. During the war Dr. Smith was appointed inspector of foods under the Local Government Board.

Yet with all his work he found time to devote to sport and country pursuits which he loved. He was a first-class shot, an excellent fisherman, and an authority on game birds. He was attached to the staff of the *Field*, to which journal he made many notable contributions, chiefly in connexion with animal pathology. In this connexion he conducted several investigations of great importance to sportsmen and contributed chapters to "The Grouse in Health and Disease" and "Tegetmeier on Pheasants." Dr. Smith was enthusiastic and indefatigable in everything which he undertook and he worked assiduously up to his death. His ability and charm of manner endeared him to all.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council on March 13th, Sir John Bland-Sutton, President, in the chair, licences to practise dentistry were conferred upon the following:—

A. V. Adams, Durham; F. E. H. Andersen and J. L. Anderson, Royal Dental; F. F. Anslow, London; A. R. H. Bennett, Guy's; C. V. Berry, Middlesex and Royal Dental; W. E. Berwick, C. E. Bowen, F. F. Brayfield, and W. E. Brigham, Guy's; H. A. Brown, J. N. Brummer, and W. A. Cannell, Royal Dental; L. M. Cartwright, Guy's; R. Chase, Royal Dental; J. W. Cooper, Bristol; W. M. Cowper, Royal Dental; F. H. R. Davey, Durham; F. G. Davies, Guy's; H. L. Davies, Royal Dental; E. Dixon, Leeds; H. M. Doubleday, Guy's; C. E. Down, Bristol; V. R. Estment, Guy's; H. B. Furniss, Leeds; G. V. Gibbs, Royal Dental; J. L. Gordon, London; G. L. Gould, Guy's; R. Hale, Royal Dental; D. S. Hammond-Williams, Guy's; M. W. Harvey, Royal Dental; R. M. Hastings, A. Hirschberg, and A. L. Hodgkinson, Guy's; H. Ihsan, Royal Dental; A. R. Jackson, Guy's; F. C. Jackson, Liverpool; H. H. Jager, Royal Dental; O. P. James, Guy's; H. P. Jeffery and A. J. Jordens, Royal Dental; L. S. J. Kanaar, Guy's; A. C. King, T. S. Latham, and R. R. Laver, Royal Dental; W. E. Leaver, E. R. Longhurst, and W. C. McGhee, London; P. J. Malone, Royal Dental; V. J. Matthews, Univ. Coll.; C. A. L. Meredith and D. G. Moffatt, Royal Dental; G. J. Moore, Birmingham; J. R. A. Moore, Guy's; E. W. G. Moran, Univ. Coll.; D. B. Muller, Royal Dental; V. W. Percival, R. G. Pengelly, and S. A. Pleasant, Guy's; Muriel Possener and W. E. Potter, Royal Dental; H. J. Ravenscroft, Leeds; J. F. S. Reynolds, Guy's; D. G. Ritchie, London; W. R. S. Robertson, Royal Dental; A. W. Shovelton, Birmingham; D. L. Simpson, Univ. Coll.; T. H. Smailes, Royal Dental; V. H. Tapp, Sheffield; F. R. Taylor, Guy's; G. Thom, Royal Dental; G. T. Thompson, Guy's; D. G. Thomson, Royal Dental; A. E. Tidd, J. B. F. Tunstall, L. P. Tupling, and A. E. J. Van Noorden, Guy's; G. Wasif and A. Wendel, Royal Dental; and F. S. S. Whiter, London.

Museum demonstrations will be given in the Theatre of the College in Lincoln's Inn-fields on Fridays and Mondays during March and April at 5 P.M., as follows: March 28th, Sir Arthur Keith, Specimens illustrating the Various Mal-developments of the Palate; 31st, Mr. C. E. Shattock, Lymphatic Glands; April 4th, Sir Arthur Keith, Development and Surgical Anatomy of the Nasal Air Sinuses; 7th, Mr. C. E. Shattock, Osteomyelitis; 11th, Sir Arthur Keith, Irregularities in the Growth of the Palate and of Eruption of the Teeth; 14th, Mr. C. E. Shattock, Tumours of the Colon. The demonstrations are open to advanced students and medical practitioners.

HUNTERIAN SOCIETY.—The third dinner meeting of the Hunterian Society will be held at Simpson's Restaurant, Cheapside, London, on March 24th, at 7.30 P.M. Dinner will be followed by a discussion on Rheumatics, which will be opened by Dr. F. J. Poynton.

CANCER HOSPITAL, LONDON.—The annual dinner of the hospital will take place at the Langham Hotel on Wednesday, April 2nd, at 7.45 P.M., with Mr. W. Ernest Miles in the chair. Tickets may be obtained on application to the Registrar, Cancer Hospital, S.W. 3.

ROYAL INSTITUTION OF GREAT BRITAIN.—The Friday evening discourse at 21, Albemarle-street, W., on March 28th, at 9 P.M., will be delivered by Prof. Hugh MacLean on Insulin. On March 27th, at 5.15 P.M., Mr. D. S. M. Watson will deliver the second of two lectures on Evolution To-day.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION: SPECIAL COURSES.—A two weeks' intensive course will be given at the London Temperance Hospital, Hampstead-road, from March 31st to April 12th. The course will include practical demonstrations each morning from 10.15 to 12.15, ward rounds and out-patient clinics in the afternoon from 2 to 4 P.M., and special demonstrations on Saturdays at Bethlem Royal Hospital and the Royal Westminster Ophthalmic Hospital. A clinical lecture will be given each day at 4.30 P.M. (to which members of the profession are invited), the first, on March 31st, by Sir Humphry Rolleston, being on the subject of Jaundice. Among other lecturers will be Mr. V. Zachary Cope, Mr. Ernest Clarke, Dr. Soltau Fenwick, and Mr. Ernest W. Miles. A three weeks' course on Ophthalmology will be given at the Royal Westminster Ophthalmic Hospital from March 31st to April 17th. In addition to clinical work each afternoon special demonstrations will be given twice a week on Medical Ophthalmology and Methods of Examination. Copies of the syllabus and further particulars will be forwarded on application to the Secretary to the Fellowship of Medicine, 1, Wimpole-street, W. 1.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—A meeting of this society will be held at the X ray department of the Manchester Royal Infirmary on March 27th at 3.15 P.M., when Dr. A. E. Barclay will give a demonstration dealing with the differential diagnosis of tuberculosis.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—A general meeting of the Association will be held at 11, Chandos-street, London, W. 1, on April 9th at 5 P.M., when Mr. Ernest Clarke, F.R.C.S., will read a paper on the Care of the Sight of School-children.

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN.—Scholarships of the total value of £1100 will be awarded in May and July of this year. Full information and forms of application can be obtained from the Warden and Secretary, 8, Hunter-street, London, W.C. 1.

OPHTHALMIC BENEFITS FOR INSURED PERSONS.—A group of ophthalmologists especially interested in this subject have formed themselves into a committee in order to support the British Medical Association in any action that may be taken to secure a working arrangement for the treatment of insured persons by duly qualified ophthalmic surgeons. "Optical benefit," as it is described in the insurance regulations, is dealt with in different ways by the various approved societies, but in only one society is any satisfactory arrangement made to provide for the insured the services of competent ophthalmic surgeons. This is unfair to insured persons and most serious for the future of ophthalmology in this country. A meeting to receive the report of the above committee and to consider their proposed programme will be held in the Council Chamber of the British Medical Association, 429, Strand, London, W.C., on March 27th, at 5.30 P.M. The support of ophthalmologists is requested, and any who desire to attend and would like to receive further particulars are asked to address their letters to the Ophthalmic Benefit Committee, 30, Finsbury-square, London, E.C. 2.

LONDON COUNTY COUNCIL AND DETENTION OF LUNATICS.—The Mental Hospitals Committee of the London County Council has prepared a lengthy report on the precautions and safeguards which exist to prevent detention of sane persons in the Council's mental hospitals. After reviewing in detail the existing procedure for admission, the Committee point out that the Council has made more than one endeavour to secure uniformity of practice, by seeking legislative authority for the establishment of receiving houses in London, to be administered by the Council, to which prospective parish cases could be admitted for observation, and where certification could be carried out by expert practitioners under uniform conditions. The legislation which the Council promoted never passed both Houses of Parliament. The Committee further explain that patients in county and borough mental hospitals enjoy a "material safeguard against improper detention," inasmuch as these institutions are managed by a committee appointed by the responsible public authority. The Subcommittees of the Mental Hospitals Committee meet fortnightly, and it is a statutory duty for at least two members together, once at least in every two months, to inspect every part of the hospital at which they serve, to see every patient, and afford full opportunity of complaint, and sign records of their inspections. Every private patient has the right to request a personal and private interview with a member of the visiting committee. Most discharges follow a recommendation by the medical officer, but the visiting committees do not necessarily rely solely on the medical staff, and may themselves institute inquiry as to the fitness for discharge of any patients. In the course of a debate on the Committee's report, Mr. Watts expressed the hope that the Committee would take a very strong view with regard to "private lunatic asylums." It should not be in the power of any individual to exploit mental disease. Improper detention occurred largely in such institutions, and although the cancellation of licences might involve claims for compensation, he believed that, in view of the state of public feeling, the Council should accept the risk. Dr. Alan Randle, the recently appointed vice-chairman of the Labour Party on the Council, said he would be sorry if only specialists were consulted in the matter of certification, because they had been so long removed from the ordinary conditions of human life that they might not even be able to detect insanity. The general practitioner, who was more in touch with the ordinary habits and activities of his patients might, if he suspected insanity, call in the assistance of a specialist, who would probably be better qualified to determine the exact type of insanity, if insanity were present. But it was common knowledge that the trouble with the specialist on any subject was the danger of his recognising his "speciality" in almost every case brought to his notice.

LADIES' MEDICAL GOLFING SOCIETY.—The spring meeting will be held at Moor Park Golf Club, Rickmansworth, on March 27th. In the morning a medal round will be played and in the afternoon foursomes against bogey. Entries should be sent to the hon. secretary, Mrs. Laming Evans, 50, Seymour-street, London, W. 1.

NATIONAL LEAGUE FOR HEALTH, MATERNITY, AND CHILD WELFARE.—The annual general meeting of the League and of the National Association for the Prevention of Infant Mortality will be held to-day (Friday, March 21st) at Carnegie House, 117, Piccadilly, London, W., at 4 P.M., with Dr. G. F. Still in the chair. Miss Margaret Bondfield, M.P., will speak on Mothers' Pensions, and Miss Eglantyne Jebb, hon. secretary of the Save the Children Fund, will speak on the Children's Charter.

DEAL: OPENING OF WAR MEMORIAL HOSPITAL.—On March 17th Prince Henry opened the hospital which has been erected, free of debt, at a cost of about £20,000, as a memorial for Deal, Walmer, and district, commemorating some 500 men from nine parishes who gave their lives in the war.

HARNETT *v.* BOND AND ADAM.—At a conference on the bearings of this case, held at the instance of the British Medical Association, it was decided in view of the pending appeal to appoint a small representative committee to watch the situation on behalf of the medical profession and to take such action as may be considered necessary. Those present at the conference included representatives of the British Medical Association, the Medico-Psychological Association, the Medical Women's Federation, the Medico-Legal Society, the Medical Defence Union, and the London and Counties Medical Protection Society.

MENTAL AFTER-CARE ASSOCIATION.—At the annual meeting of the Association held at the Mercer's Hall, London, on March 11th, Sir Charles Wakefield being in the chair, Sir James Crichton-Browne said that the Association had during the past year afforded relief to 1042 patients, each of whom had given excellent testimony to their treatment while in various mental hospitals, and expressed readiness to return should a mental relapse necessitate it. In the report, presented by Dr. Henry Rayner, chairman of the Association, it was stated that since its formation after-care associations had been established in several European countries, in the United States, Japan, and Australia. The chief object of the Association was to restart in life all persons who were convalescent, or had recently recovered from mental illness.

MEDICAL SOCIETY OF LONDON: ANNIVERSARY DINNER.—The 101st anniversary dinner of the Society was held at the Grand Hotel on March 12th, Dr. Herbert Spencer presiding. The toast of the evening was proposed by Sir Humphry Rolleston, who gave a sympathetic account of the foundation of the Society by Lettsom on democratic lines, the first Roll of Fellows consisting of 30 physicians, 30 surgeons, and 30 apothecaries. Dr. Spencer, in responding, said that in one more year the Society would attain the reputed age of Thomas Parr when he died. There were now 620 Fellows, 19 having joined in the course of the year. The concerted research on the results of operation for cancer of the breast was, he said, making progress. Dr. H. A. Des Vœux, in proposing The Services, alluded feelingly to the self-sacrificing labours during the war of the medical officers and of the mercantile marine which had involved much heroism but little glory. Surgeon Vice-Admiral J. Chambers, in responding, spoke of the dangerous plight in which the economic campaign had placed the Naval Medical Service which could not obtain the needed candidates. Better conditions had been provided in the Service for study, work, and research, and he appealed to the teaching schools for their help. Sir John Bland-Sutton proposed The Visitors in words of gentle raillery, coupled with the names of Mr. J. Wheatley, M.P., Minister of Health, and Dean Inge. Mr. Wheatley, in replying, described the office of Minister of Health as one of the dangerous trades, for, since 1919, five men had filled the position. His own relation to medicine was intimate, for he had given his only two children to the medical profession, seeing therein an opportunity, not of making a fortune, but of leading a useful life. He was looking forward to a time when the philosophy of human service was given its proper place in the education of the race; even now medicine was overflowing its scientific limits and coming into relation with other social service. Dean Inge, in his reply, added to the gaiety of the evening. The toast of The President was proposed by Dr. A. F. Voelcker and received with acclamation. Dr. Spencer said how much the Society owed to its hon. secretaries, Mr. T. P. Legg and Dr. F. S. Langmead.

Parliamentary Intelligence.

HOUSE OF COMMONS.

TUESDAY, MARCH 11TH.

Law Relating to Coroners' Inquests.

Mr. DIXEY asked the Home Secretary whether, in view of the general feeling as to the non-desirability of inquest proceedings and magisterial investigations in murder and manslaughter cases being conducted approximately at the same time in different courts and the possible hardships resulting therefrom, he would consider appointing a committee to inquire into the whole matter.—Mr. HENDERSON replied: A Bill for amending the law relating to coroners' inquests is now under consideration, and this is one of the many important points which are receiving attention.

Pauper Lunatics in Asylums.

Major CHURCH asked the Minister of Health whether the Government proposed, in view of the heavy financial burdens imposed on boards of guardians, to introduce legislation increasing the Exchequer grants in respect of pauper lunatics in asylums and making provision for new grants in respect of pauper lunatics, imbeciles, and epileptics maintained under the care of Poor-law authorities in accordance with the recommendations made by the Kempe Committee in 1914.—Mr. WHEATLEY replied: I regret that I cannot give any undertaking as to the introduction of legislation for this purpose.

Medical Officer of Parkhurst Prison.

Mr. HAYES asked the Home Secretary whether the medical officer's duties at Parkhurst Prison were wholly or in part subject to the control or direction of the governor or whether the medical officer was directly responsible to the Prison Commissioners.—Mr. HENDERSON replied: The Governor of Parkhurst Convict Prison is the chief officer to whom the other officers are subordinate, but the medical officer has entire responsibility to the Commissioners, through the governor, for the medical treatment of the convicts.

Case of Harnett v. *Bond.*

Mr. SCURR asked the Minister of Health whether, in view of the verdict of the jury in Harnett *v.* Bond, he proposed to suspend Dr. Bond from acting as Lunacy Commissioner pending the decision of the Court of Appeal.—Mr. WHEATLEY replied: Without entering into a discussion of a case which is still sub judice, I would draw attention to the fact that Mr. Justice Lush, in the course of the discussion which took place in court after the jury had returned their verdict, stated that he agreed that there was no evidence of any dishonesty or *mala fides* on the part of Dr. Bond. In view of this fact and of Dr. Bond's long and distinguished record of public service and his eminent position in the scientific world, I see no reason to take such action as is suggested in the hon. Member's question.

Mr. LANSBURY asked the Prime Minister whether he would cause to be laid upon the Table of the House of Commons the minutes of evidence in the case of Harnett *v.* Bond before any estimate was submitted to the House for the purpose of indemnifying Dr. Bond; and whether he would state on what ground this case was being taken to the Court of Appeal at further cost to the public.—Mr. WHEATLEY replied: The transcript of the shorthand notes of the evidence is extremely bulky, and such copies of it as are available are, I understand, required for the purposes of the proceedings in the Court of Appeal. After the appeal has been disposed of, I will consider whether it is practicable to make the transcript available for the information of hon. Members. The answer to the second part of the question is that the case is being taken to the Court of Appeal in the public interest.

Remuneration of Panel Doctors.

Sir KINGSLEY WOOD asked the Minister of Health whether he was now is a position to bring forward his proposals relating to the increased payment proposed to medical men on the panel lists.—Mr. WHEATLEY replied: The matter referred to by the hon. Member is still under consideration, and I am not yet in a position to make a statement on the subject.

The Spahlinger Treatment.

Sir WALTER DE FRECE asked the Minister of Health the present attitude of the Government with regard to the Spahlinger treatment.—Mr. WHEATLEY replied: I am anxious to arrange for a scientific investigation of this method of treatment in this country, and have personally given Mr. Spahlinger assurances to that effect.

THURSDAY, MARCH 13TH.

Army Medical Services.

On the motion that "the Speaker do leave the chair on the Army Estimates 1924–25,"

Mr. STEPHEN WALSH, Secretary of State for War, said that the health of the troops continued to be most satisfactory, particularly as regarded avoidable diseases, which showed a marked decrease during the year in spite of the fact that the Government had saved money on medical services. Reductions of over £100,000 had been made and the regimental establishment of the R.A.M.C. was again being reviewed.

Lieut.-Colonel FREMANTLE called attention to the very serious condition the Army was in owing to the position of the Royal Army Medical Corps. He said he had drawn the attention of the late Under Secretary for War to the lack of candidates for that Service. There were 15 vacancies advertised and only four candidates came forward; 11 vacancies were still unfilled. There was no selection whatsoever. Although two months' notice was afterwards given he believed that the result had been that for 40 vacancies only eight candidates had presented themselves. The whole force was being starved of officers from the very start. This matter required serious inquiry. The result had been to block promotion. The thing was utterly top-heavy. They had 101 colonels, 343 majors, 422 captains, and only 7 lieutenants. He believed that the same difficulty existed in connexion with the Colonial Medical Services. There ought to be a really competent inquiry into the recruitment of medical officers for public services. He would also like to know what had been done to secure coördination, particularly of the medical services, medical stores, medical personnel, and medical institutions, so that they might be used with greater economy and efficiency.

The motion that "the Speaker do leave the chair" was then agreed to.

Mental After-Care of Ex-Service Men.

Mr. PIELOU asked the Minister of Pensions whether he had invited the Mental After-Care Association to draft a scheme for the purpose of looking after ex-Service men discharged from asylums; and, if so, was he prepared to meet the cost of such scheme.—Mr. F. O. ROBERTS replied: The answer to the first part of the question is in the negative, but for some time my department has been in communication with the Mental After-Care Association with a view to exploring as to how far the Association's activities in connexion with the after-care of civilians discharged from asylums would embrace the pensioner. We welcome the coöperation of the Association, but I would remind the House that in so far as the pensioner when discharged from an asylum will need treatment or institutional care the necessary provision is made by my department.

Lunacy Law Reform.

Sir ELLIS HUME-WILLIAMS asked the Home Secretary whether, in view of the fact that the system under which alleged lunatics were apprehended and interned in asylums was not in question in the case of Harnett *v.* Bond and would not be affected by any judgment which the Court of Appeal might pronounce upon the facts of that particular case, he would proceed at once with the appointment of a committee to examine the system without waiting until the appeal could be heard.—Mr. GREENWOOD replied: The suggestion is under consideration and my right hon. friend hopes to be able to make an announcement very shortly.

Effect of the Dangerous Drugs Act.

Lieut.-Colonel FREMANTLE asked the Home Secretary the actual effect of the Dangerous Drugs Act, 1923, in checking the illicit importation of such drugs.—Mr. HENDERSON replied: The Act came into force towards the end of last May and its full effect on the smuggling of drugs into this country and on the illicit traffic generally cannot yet be estimated. The additional powers, however, given by the Act have already been found of great value, and the heavier penalties which the courts are now empowered to impose have already, it is believed, had a deterrent effect on the traffic.

International Opium Traffic.

Lieut.-Colonel FREMANTLE asked the Home Secretary the present position as to the regulation of the international opium traffic and restriction of production.—Mr. HENDERSON replied: The hon. and gallant Member will be aware that the general supervision of the traffic is entrusted to the League of Nations so far as its members are concerned, subject to the provisions of the international conventions in force, and that the League has appointed an advisory committee to deal with the subject. The proceedings of this committee and the action taken by the League and the several Governments on its recommendations will be found in the official publications of the League. As a result of the preparatory work done by the committee, it was decided at the assembly of the League last September to call two international conferences this year to consider the Far Eastern situation, and the question of the restriction of production respectively. If there is any particular point on which the hon. and gallant Member desires information, perhaps he will put down another question.

Miner's Nystagmus and Compensation.

Major ROPNER asked the Secretary for Mines whether the Home Office is considering the scheduling of nystagmus as a disease under the Workmen's Compensation Act; and whether the malady was so scheduled in any other country.—Mr. HENDERSON replied: Miner's nystagmus has been scheduled under the Act ever since 1907. As explained in reply to a question by the hon. Member for Ormskirk on the 21st ultimo, proposals for altering the description of the disease in the schedule are under consideration. I understand that compensation is payable in respect of the disease in Belgium, France, Germany, and certain States of the United States of America.

Pensions Medical Administration.

Mr. BENJAMIN SMITH asked the Minister of Pensions whether the Director-General of Medical Services had direct access to the Minister and full control of the medical branch.—Mr. F. O. ROBERTS replied: The arrangements for the control and organisation of the Ministry of Pensions follow the lines adopted in other large departments of State. The heads of the divisions are responsible to me through the Permanent Secretary for the proper control of the work of their respective branches, and I personally consult them whenever I consider it necessary to do so.

Health Insurance Finance.

Mr. TURNER asked the Minister of Health what was the total of the contributions paid into the National Health Insurance Fund in 1922; what proportion was paid by employers, employees, and the State, respectively; how much was paid out in sickness, disablement, and maternity benefits, respectively; how much was paid to panel practitioners; and what was the total balance in the insurance funds.—Mr. WHEATLEY replied: The figures relating to England and Wales for 1922 are as follows: The total of the contributions by employers and employees paid into the National Health Insurance Fund was £22,384,000, of which approximately £11,742,000 was paid by employers and £10,642,000 by employees. The State contribution which takes the form of payment of the statutory proportion of the cost of National Health Insurance benefits and administration, together with sundry grants-in-aid and cost of central administration was £7,429,000. The amounts paid out under the headings specified in the question were: Sickness benefits, £8,273,000; disablement, £3,287,000; maternity, £1,606,000; payment to insurance practitioners, £6,317,000. The accumulated funds at the end of the year amounted to about £90,000,000.

TUESDAY, MARCH 18TH.

Ex-Service Men and Malaria.

Sir FREDERIC WISE asked the Minister of Pensions how many cases of ex-Service men suffering from malaria had been dealt with this year; and how many of the cases had been refused the pension.—Mr. F. O. ROBERTS replied: During the months of January and February 189 first claims to pension in respect of malaria were decided by the Ministry. In 89 of these compensation was awarded.

Trials of Lunatics.

Sir MURDOCH MACDONALD asked the Home Secretary whether, in view of the fact that Lord Justice Atkin's committee on the procedure at the criminal trials of lunatics alleged to be insane was composed solely of the legal profession, and that its report did not meet the objections put forward in the report of the Medico-Psychological Association as regards the retention of the McNaghton rules and other disputed points, and considering that the two subjects, criminal lunacy and lunacy reform, were intimately allied, he would also refer the question of the criminal trials of lunatics to the Royal Commission now being appointed to consider the subject of lunacy reform.—Mr. HENDERSON replied: The matter will be considered.

Deafness and Pensions.

Mr. COMYNS CARR asked the Minister of Pensions if he would state on what grounds the maximum disability on account of total deafness was only 70 per cent.; and whether he would consider the possibility of increasing it to 100 per cent., so that the totally deaf man might be placed on equal terms with those disabled in other ways.—Mr. J. W. MUIR replied: The assessment for total deafness was fixed in the early days of the Ministry in accordance with the highest medical advice. My right hon. friend is not prepared to admit that it compares unfavourably with the other assessments for specific injuries laid down in the first schedule to the Royal Warrant.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 24th.

ODONTOLOGY: at 8 P.M.
Casual Communication:
Mr. E. Fish: A Compound Composite Odontome.
Paper:
Mr. G. Northcroft: The Clinical Aspect of the Care of Children's Teeth.

Tuesday, March 25th.

MEDICINE: at 5.30 P.M.
Papers:
Prof. G. Monod: Hæmatemesis without Lesions.
Dr. Oliver Heath: The Clinical Interpretation of Fever.

Wednesday, March 26th.

COMPARATIVE MEDICINE: at 5 P.M.
Paper:
Dr. N. S. Lucas: A Comparison of the Pathology of Captive Animals with that of Man (with specimens obtained from the Zoological Society's Gardens).
A discussion will follow, opened by Prof. G. H. Wooldridge.

MEDICINE.
PATHOLOGY.
THERAPEUTICS AND PHARMACOLOGY.
Members of these Sections are specially invited to attend and to take part in the discussion.

Thursday, March 27th.

UROLOGY: at 8.30 P.M.
Paper:
Mr. Clifford Morson: Treatment of Carcinoma of the Prostate.
A discussion will follow, in which Prof. Russ and others will take part.

Friday, March 28th.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)
Cases:
Dr. Vincent Coates: Progressive Lipodystrophica in a Boy of 7 Years.
Other cases will be shown.
Discussion:
On Enuresis.
To be opened by Dr. Dingwall Fordyce, followed by Mr. Ralph Thompson, Dr. J. M. Smellie, and others.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Dr. R. Dudfield: A Survey of the Mortality due to Child-bearing in London, from the Seventeenth Century.

HISTORY OF MEDICINE.
OBSTETRICS AND GYNÆCOLOGY.
Members of these Sections are specially invited to attend.

HUNTERIAN SOCIETY.
MONDAY, March 24th.—7.30 P.M. Dinner Meeting at Simpson's Restaurant, Bird-in-Hand-court, Cheapside, London, E.C., Dr. Poynton: Rheumatics.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.
FRIDAY, March 28th.—8.30 P.M., Discussion on Gonorrhœa Infection by Secondary Organisms, to be opened by Colonel E. T. Burke, followed by Dr. Lydia Henry.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
TUESDAY, March 25th.—5 P.M., Dr. Leonard G. Parsons: Wasting Disorders of Early Infancy. (First Goulstonian Lecture.)
THURSDAY.—5 P.M. (Second Goulstonian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.
MONDAY, March 24th, to SATURDAY, March 29th.—BETHLEM ROYAL HOSPITAL. Course in Psychological Medicine. Tues. and Sat., 11 A.M., Dr. Thomas Beaton and Dr. Porter Phillips: The Psychoses.—CHELSEA HOSPITAL FOR WOMEN. Daily: Operations, &c. Mon., 2 P.M., Mr. Banister: Backward Displacement. Tues., 11 A.M., Mr. Galletly: Demonstration in Wards, Gynæcological Histories. Wed., 2 P.M., Mr. Ellison: Vaginal Discharge. Thurs., 9.30 A.M., Mr. Provis: Sterility. Fri., 2 P.M., Mr. Comyns Berkeley: Cervical Fibroids.—ROYAL FREE HOSPITAL. Wed., 5.30 P.M., Dr. Heald: The Uses of other Electrical Currents.—ROYAL WATERLOO HOSPITAL. Lecture-Demonstrations, Ward Work, &c. Mon., 2 P.M., Dr. Woodwark; 3 P.M., Dr. Barron; 4 P.M., Dr. Donaldson. Tues., 2 P.M., Dr. Moon; 3 P.M., Dr. Myers; 4 P.M., Dr. Davidson. Wed., 1.30 P.M., Mr. Cairns Forsyth. Thurs., 1.30 P.M., Dr. Perkins; 2.30 P.M., Mr. Bickerton; 3.30 P.M., Dr. Tindal Atkinson. Fri., 2 P.M., Dr. Perkins; 4 P.M., Mr. Beevor. Sat., 9.30 A.M., Mr. Frankau (Operations). Further particulars can be obtained from the office at No. 1, Wimpole-street, W. 1.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith.
MONDAY, March 24th.—10 A.M., Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Simmonds: Out-patients (Surgical). 2 P.M., Mr. Simson: Diseases of Women.
TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Diseases of Throat, Nose and Ear.
WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients. 2 P.M. Dr. Pernet: Skin Department.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2 P.M., Mr. MacDonald: Genito-Urinary Department.
FRIDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 10.30 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients.
SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.
Daily 10 A.M., to 6 P.M., Saturdays, 10 A.M., to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital.
(At 4.30 P.M.)
MONDAY, March 24th.—Mr. T. H. C. Benians: Chronic Bacterial Infections of Mucous Surfaces.
TUESDAY.—Dr. J. Metcalfe: A Survey of Progress in X Ray Diagnosis.
WEDNESDAY.—Dr. J. Browning Alexander: Hæmoptysis.
THURSDAY.—Mr. J. Bright Banister: Disturbances in Micturition.
FRIDAY.—Dr. L. R. Yealland: Clinical Demonstration of Cases.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE.
CLINICAL LECTURES AND DEMONSTRATIONS.
MONDAY, March 24th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Disseminated Sclerosis: Dr. Birley.
TUESDAY, March 25th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Cerebral Topography: Mr. Armour.
THURSDAY, March 27th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Diseases of Bone: Dr. Russell J. Reynolds.
FRIDAY, March 28th.—2 P.M. Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Demonstration of Physical Exercises in the Exercise Room.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.
MONDAY, March 24th.—12 noon, Syringomyelia, Hydromyelus and Allied Conditions: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.
WEDNESDAY, March 26th.—3.30 P.M., The Central Visual Paths: Mr. Leslie Paton.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday.
All applications should be sent to the Secretary, Medical School.
J. G. GREENFIELD, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st. W.C.
THURSDAY, March 27th.—4 P.M., Mr. Fairbank: Scoliosis.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
THURSDAY, March 27th.—5 P.M., Dr. Roberts: The Lying-in.

CANCER HOSPITAL, Kensington, S.W.
WEDNESDAY, March 26th.—4.30 P.M., Sir Thomas Horder: The Nutritional Factor in Malignant Disease.

VICTORIA UNIVERSITY OF MANCHESTER MEDICAL SCHOOL.
FRIDAY, March 28th.—5.30 P.M., Prof J. C. Brash The Genesis and Growth of Deformed Jaws and Palates.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.
TUESDAY, March 25th.—4.15 P.M., Dr. J. Shaw Dunn: High Colour Index Anæmias.

MANCHESTER BABIES' HOSPITAL POST-GRADUATE LECTURES.
FRIDAY, March 28th.—5.30 P.M., Dr. Jenkins: Vaccines and their Use in the Treatment of Infants.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)
MONDAY, March 24th.—(At the Children's Hospital.) Dr. W. Johnson: Poliomyelitis.
TUESDAY.—(At the Southern Hospital.) Dr. W. Johnson: Idiopathic Epilepsy.
WEDNESDAY.—(At the Northern Hospital.) Dr. Pemberton: Diagnosis and Treatment of Abnormal Conditions in Upper Alimentary Tract.
THURSDAY.—(At the Stanley Hospital.) Dr. Wadsworth: Diabetes.
FRIDAY.—(At the Royal Infirmary.) Mr. A. E. Burroughs: Medical Ophthalmoscopy with Lantern Illustrations.

Vacancies.

For further information refer to the advertisement columns.

Ayr County Hospital.—Sen. Res. H.S. £100.
Barbados General Hospital.—Jun. Res. S. £250
Birmingham Union, Selly Oak Hospital.—Res. Asst. Med. Supt. £550.
Bradford City.—Bacteriologist and Pathologist. £750.
Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.
Bury Infirmary.—Jun. H.S. £150.
Cancer Hospital, Fulham-road, S.W.—H.S. £100.
Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—H.S. £100. Jun. H.S. £50.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Radiographer.
Coventry and Warwickshire Hospital.—Res. H.S. £150.
Croydon Union, Mayday-road Hospital, &c.—Second Asst. M.O. £300.
Dublin University, Trinity College.—Prof. of Pathology. £800.
Durham County Council Education Dept.—Asst. Sch. M.O. £600.
Evelina Hospital for Children, Southwark, S.E.—H.S. and H.P. Each £60.
Guildford, Royal Surrey County Hospital.—H.S. £150.
Guy's Hospital, Salomons Infant Welfare Centre.—M.O. £350.
Hampstead Council of Child Welfare, 27, Heath-street, N.W.—Maternity &c., M.O. £100.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S., H.P., and Asst. Cas. O. £50.
Hull City Asylum.—Med. Supt. £1000.
Keighley, Victoria Hospital.—H.S. £180.
Leeds City.—Chief Clin. Tub. O. £900.
Leeds, Ministry of Pensions Hospital, Beckett Park.—Radiologist. £600.
Leicestershire and Rutland Mental Hospital, Narborough, near Leicester.—Second Asst. M.O. £350.
London Jewish Hospital, Stepney Green, E.—Cas. O. £200.
London Lock Hospital, 91, Dean-street, W.—H.S. £200.
London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. and Med. Reg. Each 40 guineas.
Manchester, Victoria Memorial Jewish Hospital.—Secy. and Supt. £350.
Norfolk County Council.—Asst. Tub. O. £600.
Norwood and District Cottage Hospital, 77a, Westow Hill, S.E.—Hon. Anæsthetist.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. S.
Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.
Prince of Wales's General Hospital, Tottenham, N.—Two H.S.'s, H.P. Each £150. Jun. H.S. and Jun. H.P. Each £110.
Prison Medical Service.—M.O.'s. £504 14s.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S. R.M.O. £200.
Rochdale Infirmary and Dispensary.—Jun. H.S. £200.
Royal Chest Hospital, City-road, E.C.—H.P. £100.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. P.
Royal Westminster Ophthalmic Hospital, King William-street, W.C.—Asst. H.S.
St. Thomas's Hospital.—Ophth. Reg.
Sheffield Royal Hospital.—Asst. Cas. O. £100.
Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £200.
Surrey County Council.—Asst. M.O.H. £660.
Western Australia, Medical and Health Dept.—Bacteriologist and Pathologist. £708.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. Non.-Res. H.S.'s. £150 and £100 respectively.
York County Hospital.—H.P. £150.
York Dispensary.—Res. M.O. £175.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Portree, Inverness; Shap, Westmorland; Winslow, Buckingham; Wartle, Aberdeen.

Births, Marriages, and Deaths.

MARRIAGES.

CORMACK—MCRAE.—At Christ Church, Rangoon, on Feb. 5th, 1924, Major H. S. Cormack, *M.C.*, I.M.S., eldest son of John Cormack, of Corstorphine, Edinburgh, to Dorothy, only daughter of the late George William McRae and of Mrs. Isobel McRae, Felpham, Sussex.

DEATHS.

BALLINGALL.—On March 9th, at Cloudesley-road, St. Leonards-on-Sea, George Anderson Ballingall, M.D., aged 63 years.
FITZMAURICE.—On March 11th, at St. Flora's-road, Littlehampton, Richard Fitzmaurice, L.R.C.S., L.R.C.P., late of Lindfield, aged 72.
HOOD.—On March 15th, at Boundary-road, St. John's Wood, of heart failure, following influenza, Donald William Charles Hood, C.V.O., M.D., F.R.C.P., aged 76 years.
JOSLING.—On March 12th, at a nursing home in Hastings, Lieut.-Colonel Charles Langford Josling, late of the R.A.M.C.
MICHAEL.—On the 7th of March, at 7, Canfield-gardens, N.W. 6, Gustave Michael, M.B., C.M. Edin., aged 61.
WOMACK.—On March 11th, at The Croft, Finchampstead, Berks, Frederick Womack, M.B., B.Sc.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE HEALTH OF THE SOUDAN.

FOUNDATION OF A NEW MEDICAL SCHOOL.

WHILE our responsibility for the health of Lower Egypt is becoming less direct, medical administration in the Soudan remains, as before, in the hands of British officials. This fact lends interest to the report on the Administration and Condition of Soudan in 1922, prepared by the Governor-General, Major-General Sir Lee O. F. Stack. This report records the retirement on pension of, amongst other officials, Dr. E. S. Crispin, C.B.E., Director of the Medical Department, which he joined in 1904 after three years' service with the Medical Corps of the Egyptian army. He was first posted as medical officer to Halfa Province, and was subsequently transferred to the Red Sea Province just at the beginning of the development of Port Soudan; for nearly five years he had charge of that province, and carried the very difficult work of public health and quarantine to a high degree of efficiency. In 1909 he was transferred to Khartoum as assistant director of the department. In 1916 he was appointed Director and also President of the Central Sanitary Board, posts which he held until his retirement in August, 1922. In addition to his other duties, he was a member of the Governor-General's Council from September, 1919. "The present efficiency of the medical department is due," it is added, "to a large extent to the energy, personality, and powers of organisation of Dr. Crispin, and his retirement is a loss which will be keenly felt both by the medical department and the Central Government." Dr. Crispin's successor is Dr. O. F. H. Atkey.

Training of Assistant Medical Officers.

Perhaps the most noteworthy feature of the year, as regards public health, was the gratifying success which has attended the training of native assistant medical officers. Two of them carried out very valuable work in Dongola, where a severe epidemic of bilharzia had broken out in connexion with the pumping stations at Nuri and Gureir, and also at Magall and Tangassi Island; 5478 injections of antimony tartrate were made, 455 cases were cured, and these areas of infection are now clear. Their work at various hospitals in the provinces has also been consistently well reported on, and is a most encouraging sign for the future. During the summer five assistant medical officers received a course of laboratory training. It is hoped in time to give this additional microscopic training to all, so that when attached to a hospital they can carry on the necessary microscopical work—e.g., staining for, and recognising, malarial parasites, &c.

In civil hospitals the number of in-patients decreased by 922, from 18,664 to 17,742; and out-patients by 20,370, from 376,097 to 355,727. The decrease is mainly attributable to the general shortage of money and the closing down of the work at Makwar Dam. Military hospitals treated 3960 civil in-patients and 59,936 out-patients, as compared with figures of 3174 and 39,314 respectively in 1921. The increase in the number of out-patients is mainly due to a large increase of the work at Rumbek. Apart from a heavy incidence of malaria all over the Soudan, due to exceptional heavy rains, public health has been good. Malaria was especially prevalent in Khartoum and Omdurman.

Epidemics and Preventive Measures.

An epidemic of small-pox broke out last winter at Khartoum among recent immigrants from Kordofan: it spread up the Blue Nile as far as Roseires and up the White Nile as far as Kosti. Later in the summer it spread north to Atbara, Sinkat, and Port Soudan, but the outbreaks in these provinces were very limited. Fortunately both in the provinces north of Khartoum and in the Blue Nile Province, where the population is densest, vaccination has been very thorough. The total number of cases was approximately 179, of which 13 proved fatal. The number of vaccinations performed in connexion with this epidemic was 191,577. A small outbreak of cerebro-spinal fever occurred among the labourers working on the new pumping station at Wad-el-Nan in December. Vigorous measures were taken and the outbreak was strictly limited. There were 32 cases, of which 28 died.

The hospital ship (*Lady Baker*) was put in commission, and was handed over to the medical authorities at Malakal at the end of March. She returned to Khartoum at the end of June. During this period she made six tours, in the course of which many places were visited where previously the natives had had no opportunity of receiving medical assistance; 1094 natives were attended, and 1040 injections of novarsenobenzol were given. A report from Bahr-el-Ghazal Province mentions that sleeping sickness is still a formidable menace in Tembura district, but the plan initiated in 1921, of collecting the Azande into villages in

cleared areas, is being steadily followed, and should result in a considerable check to the disease. The scheme is disliked locally, inasmuch as it involves changing the habits of the people who are accustomed to live in separate homesteads in the forest. An additional district commissioner is, however, being appointed to this district for the express purpose of supervising anti-sleeping sickness measures, and it is hoped that a wider realisation of their benefit will result, and that the coöperation of the people will be secured.

The New Medical School.

During the year under review a complete medical survey was made for the first time of all boys entering the Gordon College and Omdurman School. Similar surveys, but rather less complete, were carried out at Port Soudan, Atbara, and Wad Medani schools. These surveys cannot fail to be of the greatest assistance to the teaching staff, and it is hoped to continue them every year. Very excellent work has been carried out at the Midwives School in Omdurman. In the course of the year 15 midwives received training and were granted licences. Two new hospitals, one at Kassala and the other at Halfa, have been completed and are now in use. New dispensaries have been opened at Resik in the Upper Nile Province, and at Rashad, Nuba Mountains Province. At Nahud a new hospital is in process of erection. The new building for the Medical School, Khartoum, will, it is hoped, be soon completed and ready for use.

Major R. G. Archibald, D.S.O., Director of the Wellcome Research Laboratories, reports that, in spite of the large number of routine examinations performed, researches have been carried out on various problems and progress has been maintained in all sections. In the bacteriological section the routine work has been particularly heavy; 5255 examinations, constituting a record number for this section, were carried out, while over 800 Wassermann tests were performed. Various researches have been carried out on cattle anthrax, epidemic jaundice, Malta fever, bilharziasis, sleeping sickness, and dysentery. Laboratory investigations proved the interesting fact that *Trypanosoma rhodesiense* was the cause of certain cases of sleeping sickness in Tembura, Bahr-el-Ghazal Province. A mollusc survey was carried out in a part of the province of Dongola in May. The result showed that the mollusc *Isidora innesi* was the intermediate host responsible for the spread of bilharzia in that province.

The Gordon Memorial College at Khartoum celebrates its coming of age this year and the establishment of a medical school there is the realisation of a scheme which had the warm support of the late Lord Kitchener. The close association of medical school, civil hospital, and research laboratories is of happy augury for the success of the scheme.

RESCUE AND PREVENTIVE INSTITUTIONS.

THE Public Health Department of the London County Council has issued a second edition of the handbook of information on rescue and preventive institutions. This includes a list of homes and hostels for those suffering from venereal disease, an appendix of institutions dealing with cases of mental deficiency, as well as alphabetical and classified indexes of the homes. The handbook was first drawn up by Sir William Hamer in 1921, following an inquiry made by Dr. F. N. Kay Menzies into the scope of the work done by various voluntary societies. Workers were then found to be frequently frustrated by lack of knowledge about available facilities, and information was therefore supplied in this handy and compact form. The second edition has been brought up to date, and may be purchased from Messrs. P. S. King and Son, Ltd., 2 and 4, Great Smith-street, London, S.W. 1 price 1*s.* 3*d.*

ENTRY OF MEDICAL STUDENTS IN 1923.

WITH reference to the graph which appeared on p. 579 of our issue of March 15th, it has been pointed out to us that the number of medical students who were registered last year by the General Medical Council is not a precise indication of those who actually entered upon the curriculum. A certain number of students who would, under the old regulations, have begun the study of chemistry and physics in October, only began their pre-registration work at this time, and instead of being registered in that month will probably register some time this year. It appears, further, that the northern universities are not making arrangements to bring the new curriculum into force until the current year. Consequently students who commence study there are not at present registered. There is no doubt, however, that after these corrections have been applied there will remain a considerable drop in numbers, although it will not be so large as is indicated by the graph, when 1923 and 1924 are reviewed together. By reason of the revised curriculum the year 1923 was in some degree an interregnum.

AN IMPROVED MEDICAL CASE.

THE disastrous results which may follow the hasty picking up of a bag of the attaché type which has not been properly fastened are entirely obviated by an extremely ingenious handle fitted to the bags made by Messrs. E. Gonville and Co., of 37, Walbrook, London, E.C. 4. This handle, which in appearance is similar to the ordinary bag handle, is split longitudinally down the centre, one half being fixed to one side of the bag, and the other half to the opposite side. The bag cannot be closed without first fitting together the extreme ends of each half of the handle, and then closing the halves as one would shut a purse. The two halves of the handle are provided with a catch and a lock and key. The action both of opening and shutting the bag is simply and quickly performed. The prices range from 17*s.* 6*d.* for a 14 inch, to 25*s.* for a 20 inch bag. Special sizes are made to order.

TSETSE-FLY INVESTIGATION IN NIGERIA.

A NOTE on the tsetse-fly investigation now in progress in Nigeria by Dr. T. B. Adam, Acting Director of the Medical and Sanitary Service, is included in the address delivered by the Governor, Sir Hugh Clifford, at the Second Session of the Legislative Council held at Lagos on Feb. 11th.

The base camp for investigation during the past year has been situated in an important tsetse belt which cuts across the main roads between Azare and Hadeija in the Kano Province. An intensive study has been made of the trypanosome infections and food of the two species of tsetse, *G. morsitans* and *G. tachinoides*, which occur in this area. In order to obtain a continuous record of these features it has been necessary to make daily dissections of the flies. In all some 30,000 such dissections have been carried out, and from the figures so obtained mathematical curves have been prepared which show a regular rise and fall according to the movements of the game animals and the changes of the seasons. A most careful study of the breeding haunts of the flies has been prosecuted and a knowledge of the seasonal variations of breeding has been obtained, so that it is now considered that sufficient information has been acquired to justify large-scale experiments. The objective of these experiments is the determination of the vexed question of the relationship of *G. morsitans* and big game. Treatment of cases of sleeping sickness by Bayer "205" has been undertaken and the immediate results are most satisfactory. Patients brought in moribund for the first injection have been known to walk in with assistance for the second treatment two days later. The permanence of these results has yet to be tested, and much work remains to be done in determining the number of doses which can be regarded as effective in various stages of the disease, at different ages, and in all the different conditions that may be met with.

SANTOPERONIN.

IN our notice of a new anthelmintic (THE LANCET, Feb. 23rd, p. 398) we reported that it differed from the maker's description in containing sulphate. Since then we have received further reports on this substance, according to which it is a mixture containing inter alia salicylic acid as well as sulphate, and cannot be regarded as a definite chemical compound. Investigations made at the State Institute for Pharmaco-Therapeutic Investigations, Leiden, Holland, suggest that the anthelminthic action is uncertain and inferior to that of santonin itself.

Messrs. H. K. Lewis and Co., Ltd., have arranged to act as agents in the British Isles for the publications of the Chemical Catalog Company, U.S.A., and will supply a list of these works on demand. All the principal books are kept in stock.

R. G.—The word "apostemate," although perfectly good sixteenth-century English, has long become obsolete, and "suppurate," which is good English Latin, has taken its place. There seems no sufficient reason for its revival. Even when "apostemate" and kindred words were current they seem to have been used uneasily, for all kinds of spelling are to be found—e.g., apostemate, apostumate, aposteme, apostume, aposthume, imposthume, apostem.

R. S.—There seems no doubt that the medical officer at an infirmary is entitled to sign lunacy certificates unless he is disqualified for the reasons stated in the Act and printed on the back of the certificate. There is much to be said for the officer employed by the guardians himself signing the certificate, for the guardians have to pay, and may reasonably require their officer to examine. No doubt it is advisable for anyone who has to sign lunacy certificates to join one or other of the medical defence societies, and, in addition to this, he would be prudent to keep a careful note of the circumstances in every case.

An Address

ON

VITAMINS AND THE BORDERLAND BETWEEN HEALTH AND DISEASE.

Read before the Section for Maternity and Child Welfare of the Society of Medical Officers of Health on Jan. 16th, 1924.

BY W. CRAMER, D.SC. EDIN., PH.D. BERL., M.R.C.S. ENG.

IT has been said that the two chief causes of disease and death are food and drink. But when we sit down to dinner we do not merely supply our bodies with fuel and in doing so run the risk of disease and death. If we have chosen our food wisely and prepared it carefully, it will supply us with certain stimulating drug-like substances which have a tonic effect on specific tissues and which, so far as we know at present, cannot be replaced by any other known drug. These substances are the vitamins, or as Hopkins originally called them, the food-accessory substances.

According to the current conception it would not be paradoxical to define a vitamin as an unknown substance present in the food having an unknown action. It has, in fact, been denied that they have any positive action. Their existence was recognised by what happened not when they were present but when they were absent. There is nothing extraordinary in this fact since the endocrine function of many organs such as the ovary, the testes, and the thyroid was recognised by what happened after their removal.

The effects produced by the absence of vitamins are characteristic and specific for each vitamin. In every case the administration of the missing vitamin relieves the specific condition with a certainty and a rapidity which is one of the most striking and unique phenomena in medicine.

VITAMINS IN ORDINARY DIET.

Not infrequently it is said that these facts, although important and interesting from the scientific point of view, have little bearing on practical problems of nutrition, because under the conditions of modern civilised life deficiency diseases are rare. The ordinary mixed diet on which we live is said to contain sufficient vitamins to prevent the onset of these diseases. This view—expressed not only by clinicians who are sceptical about the application of the results of laboratory experiments to man, but even by those who are engaged in the actual study of vitamins—I hold to be mistaken. It is true that there is no difficulty in constructing from the ordinary articles of food a diet which contains an ample supply of vitamins. But the diet of large classes of the population is in fact so poor in vitamins as to impair health, especially in children. This fact is due partly to economic reasons, but mainly to ignorance on the part of the consumer, and on the part of those concerned with the preparation of food on a large scale before it reaches the consumer—especially the milling of flour for bread, the manufacture of margarine, and the tinning of meat and vegetables. Again, a misconception of the mode of action of vitamins has led to under-estimation of the practical importance of these substances in nutrition, even by many ardent supporters of the vitamin theory; and the harmful effects of a restriction in the intake of vitamins, insufficient in itself to produce an obvious and typical deficiency disease, have received little attention. In the numerous investigations on vitamins, animals in full health on an ample supply of vitamins have been compared with animals in which a typical deficiency disease had developed as the result of the complete absence of one or other vitamins. But the borderland between health and disease, the borderland created by a restriction in the intake of vitamins, has remained unexplored.

KERATOMALACIA IN DANISH AND ENGLISH CHILDREN.

Before dealing with this unrecognised aspect of the vitamins, I should like to point out that even in the immediate past deficiency diseases were of more frequent occurrence even in Europe and in this country than is generally recognised. The cause and cure of infantile scurvy or Barlow's disease, now known to be due to a deficiency in the vitamin C, was, of course, known long before the vitamin conception was developed. But the cause and cure of a condition of defectivenutrition in children, which is normally associated with an affection of the eyes, has only recently been understood as being due to a deficiency in the fat-soluble vitamin A. Curiously enough, the European country in which this condition has occurred with exceptional frequency is Denmark, one of the largest producers of butter and dairy produce which are the vehicles of vitamin A; for Denmark exported too much of its vitamin A and substituted for it margarine devoid of this vitamin. The cases described very fully by Bloch[1] occurred in a group of children kept in an institution. Other two groups of children kept in the same home did not develop the disease. The diet of these three groups differed: Group A, which comprised infants and delicate children, had chiefly whole milk and milk puddings. This group did not develop the disease. The older children, Group B, received a more varied diet, which may be given fully for its interest:—

Breakfast: Oatmeal, bread and beer soup, and a little fresh milk.
Mid-day dinner:—First course: Milk puddings, oatmeal, soups (fruit juice or meat broth). Second course: Fish or meat and mashed potatoes.
Afternoon: Cocoa with bread and margarine.
Evening: Milk pudding, bread and margarine.

The margarine was vegetable margarine and all food was prepared with this margarine. The milk used was half-skimmed milk. The children received no butter, cream, or eggs. Group B was divided in two subsections, B1 and B2. In Group B1 the eye disease developed, while the Group B2 remained free. And it was found that the group that remained free had received regularly a small amount of whole milk for breakfast, while the matron who looked after the third group in which the eye affection appeared, had not given whole milk for breakfast. The disease disappeared when cod-liver oil was given. Here, therefore, in spite of a varied and apparently nutritious diet an almost complete deficiency in vitamins was established.

Similar outbreaks of epidemics which were associated with an eye affection have occurred in this country during the last 40 years in various industrial schools and have been recorded in the literature. The last recorded outbreak was in 1911 and was investigated by Dr. J. P. McGowan and Dr. C. McNeil.[2] Clinically, the outstanding feature of these epidemics is described by the authors as a "distorted" pneumonia which may vary in type from a fulminating rapidly fatal type to an abortive or latent group of febriculæ. The authors draw special attention to the fact that there was also very prevalent in this school a chronic granular conjunctivitis. McGowan and McNeil clearly recognised the non-contagious nature of the epidemic, but they were unable to explain the nature of the disease or to recommend a rational treatment. The diet had been carefully drawn up by a high scientific authority. At that time experiments on animals had not yet clearly revealed the existence of vitamins. The discovery of these food factors, the distinction between the vitamin A and B, and the experimental production of an eye affection by withholding vitamin A from the food date from the years immediately following this outbreak. When the next outbreak occurred in the same industrial school in 1919 Dr. Marshall Findlay, who was sent down to investigate the matter, was struck by the resemblance

[1] Journal of Hygiene, 1921, xvii., 283.
[2] Edinburgh Medical Journal, 1913, x., 201.

of this condition to the keratomalacia produced experimentally in rats by vitamin A deficiency. He at once inquired into the food provided to the boys and found that for a special reason the food was cooked in metal containers provided with a lid which was screwed down during the process of cooking. The food was therefore subjected to a process of autoclaving which is now known to destroy vitamin A. Dr. Findlay recommended a supply of cod-liver oil and swede juice, and the disease disappeared. I am greatly indebted to Dr. Findlay for allowing me to make use of this important and hitherto unpublished information.

There may be other conditions of malnutrition, especially in children, in which a deficiency of vitamins may prove to be an important ætiological factor. But it is not my intention to-night to discuss what diseases may, or may not be, due to vitamins. The fact that specific diseases can be produced by the absence of specific vitamins and can be cured as by magic by supplying the missing vitamins is striking and impressive. But this very impressiveness has obscured other phenomena related to the vitamins which, though less obvious and less striking, are of at least equal practical importance. I refer to what, for want of a better name, I have called the effects of "vitamin underfeeding." This may produce conditions of obscure ill-health, or it may not go as far as that, merely leading to an imperfect development of the organism, to deviations from the optimum which cannot even be called deviations from the normal. These effects are so little obvious that they have up to now been overlooked; in fact, according to the current conception of vitamins, they should not occur at all.

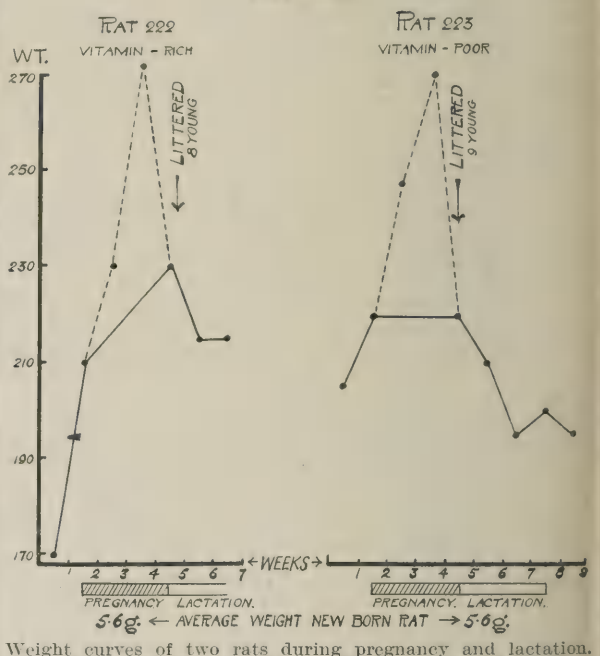
The following considerations will, perhaps, make my point clear. As a rule, we think of disease as an event superimposed upon the healthy organism. In such diseases as cholera, measles, syphilis, influenza, whooping-cough, diphtheria, and in fact all infectious diseases, we date the disease from the moment when infection occurred, even although the symptoms may not make their appearance for several days or weeks. There is a sharp dividing line between health and disease in these cases. Even in such a disease as cancer we date, mentally at any rate, the onset of the disease from the moment that a cell or a group of cells has acquired the property of autonomous growth which is the outstanding characteristic of a cancer cell. But in other groups of diseases it is impossible to date the onset of the disease. In such conditions as, for instance, myxœdema, Addison's disease, diabetes mellitus, acromegaly, it is, as a rule, impossible to draw even mentally a dividing line which would separate sharply a subnormal functioning of an endocrine organ from the actual disease. There is a borderland between health and disease when we consider the functional activity of the endocrine organs, and there is such a borderland also when we consider vitamins.

Animal Experiments on Vitamin Underfeeding: Evidence of Imperfect Development.

Experiments on animals have demonstrated that a highly differentiated organism requires for its full development a *maximum* supply of vitamins especially during the early period of its life. Any restriction of this supply leads to an imperfect development without necessarily producing obvious disease or obvious ill-health and without even preventing the process of reproduction. The result is an undersized, ill-bred population with a diminished resistance to disease—a "C 3" population. And I wish to stress this point: These results were obtained not with an artificial diet specially constructed with the intention of restricting the vitamin-supply but with a natural diet of bread and water, maize and rice, which was fixed upon empirically many years ago, after a good deal of experience, because it enabled this laboratory to maintain and rear a large population of rats economically and efficiently for experiments in connexion with cancer. Such experiments are of long duration, and it is essential for their success that spontaneous diseases and epidemics should not intervene. Fresh greenstuff was intentionally excluded from the diet, because it was found to give rise to epidemic outbreaks of enteritis.

From the practical point of view the diet appeared, therefore, to be adequate. In the light of our present knowledge it is clear, however, that its content in vitamins is restricted. It is also defective in respect of the proportion in which the inorganic elements are present. The diet contains little calcium and a preponderance of the acid-forming elements. Neither of these defects are sufficiently severe, however, to produce obvious ill-health or to interfere with the breeding and rearing of the stock. When this diet was supplemented by the addition of small amounts of preparations rich in vitamins, such as cod-liver oil for vitamin A and a yeast preparation for vitamin B, the stock improved markedly as indicated by a more rapid growth. This was especially striking when the pregnant and lactating mother was kept on the vitamin-rich diet. So far as the mother was concerned there was always a loss in weight of the mother during the period of pregnancy and lactation on the vitamin restricted laboratory diet alone, while with the addition of vitamins the mother actually gained in weight in most cases and never showed a loss (see Chart A). This means that on the vitamin-restricted diet the mother had to sacrifice her own tissues in order to nourish her offspring. The weight at birth of the litter on the whole was not smaller on the vitamin-restricted diet, but was actually larger.[3] The growth of the embryos in utero was, therefore, quite unaffected by the vitamin-supply. But as soon as the animals are born and become dependent upon the functional activity of the alimentary canal, the difference between the two diets becomes apparent. Not only the increase in weight and size, but also development, such as the growth of the fur, is more rapid on the diet supplemented with

Chart A.



Weight curves of two rats during pregnancy and lactation. Rat 223 was on the ordinary laboratory diet and therefore vitamin underfed. Rat 222 received the same diet supplemented with cod-liver oil and marmite. The broken line indicates the increase in weight during pregnancy due to the development of the embryos in utero. Note the pronounced loss of weight of the vitamin underfed rat during lactation.

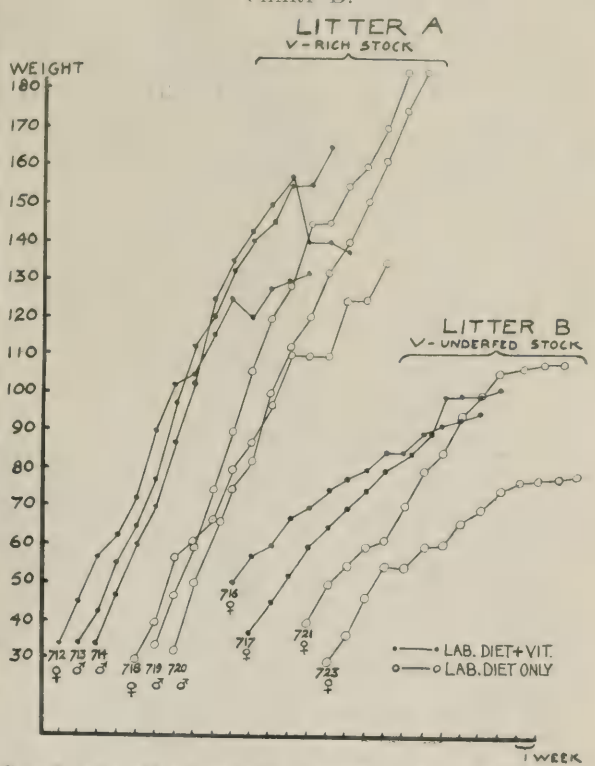
[3] Full data of these experiments have been given in a previous paper "On Vitamin Underfeeding," Brit. Jour. Exp. Path., 1922, iii., 298.

cod-liver oil and yeast. This difference persists and becomes more marked when after weaning the difference in the two diets is maintained.

We have now for nearly three years kept two stocks of rats on these two diets. The stock kept on the laboratory diet alone is called the "vitamin-underfed stock." In order to demonstrate this difference I have brought here two litters of the same age from these two stocks. These rats are now five months old, are sexually mature, and have passed the period of most active growth. The rats from the underfed stock are obviously undersized, but otherwise look normal, healthy animals. If one did not know their age one would from their weight and size take them to be much younger animals of the vitamin-rich stock. But there is a much more important and significant difference between the animals from these two stocks than mere difference in weight and size. This difference, which affects the whole make-up of the animal, manifests itself in different ways. For instance, when young rats from the vitamin-underfed stock are placed on a diet free from vitamin A their growth stops at once; within 8–10 weeks at the latest they develop the typical eye lesion and look ill and emaciated and die from some infective condition. The rats from the vitamin-rich stock continue to grow for a considerable time. Their growth may sometimes be more rapid than that of rats kept on the ordinary diet. For three or four months they look perfectly well and healthy, and the typical eye lesion develops two or three months after the death of the rats from the vitamin-underfed stock. I have maintained two rats on a completely vitamin-free diet for nine months before the eye lesion developed. These differences are obtained invariably and have been confirmed by other observers.

But this difference between the vitamin-rich and the vitamin-underfed stock manifests itself even when there is no attempt to produce a deficiency disease. When the diet of rats from a vitamin-underfed stock is supplemented with an ample supply of vitamins their growth may be a little improved, but it is not as rapid as the growth of the animals from the vitamin-rich stock. They never catch up in weight and size with the animals from the vitamin-rich stock. In a paper published a year ago I have given the chart of such an experiment.[4] But sometimes the growth is not improved at all. Conversely when rats from a vitamin-rich stock are subjected to vitamin underfeeding their growth is only slightly impaired and sometimes is not impaired at all. Results of this kind cannot be explained by assuming that this vitamin-rich stock has in its tissues a store of vitamins on which the animals can draw. In Chart B the result of another such experiment is given. It refers to two litters of known and equal age: Litter A from a vitamin-rich stock, litter B from a vitamin-underfed stock. When seven weeks old three rats of litter A were placed on the laboratory diet enriched with cod-liver oil and marmite. Similarly, three rats of litter B from the vitamin-underfed stock were placed on the vitamin-rich diet, while the other three rats were kept on the laboratory diet alone. Two rats died at the beginning of the experiment from lung infections and are not represented in the diagram. It will be seen from Chart B that in this experiment the growth of rats which came from a vitamin-rich stock and which since birth had received an ample supply of vitamins was not impaired by subsequent underfeeding of vitamins. Conversely, rats which came from a vitamin-underfed stock and for the first seven weeks after birth had been subjected to vitamin underfeeding, were not able to respond to an increased vitamin-supply by increased growth. They had received permanent damage as the result of the unfavourable dietetic conditions to which they had been subjected. Since rats of litter B come from a stock which had been subjected to vitamin underfeeding for several generations, we cannot differentiate between the effects of this underfeeding on the litter itself and on the previous generations. There is considerable evidence from the work of other workers, especially Orbone and Mendel, and McCollum and his collaborators, that defective nutrition has remote effects with cumulative action through successive generations, so that the physical condition of the stock becomes progressively worse. To simplify the argument we describe this experiment as underfeeding of litter B. But the possibility that the condition of this litter is due partly to the underfeeding practised

CHART B.



Growth curves of two litters A and B of equal age. For further explanation see text.

on preceding generations adds further emphasis to the danger of vitamin underfeeding. Definite functional and anatomical differences can be noticed between certain corresponding organs and tissues of these two stocks. The lymphoid tissue of the vitamin-rich stock is functionally and anatomically more fully developed, and this is reflected by an increase in the number of lymphocytes in the circulating blood. The same holds good for the intestinal mucous membrane; in fact, in the vitamin-poor stock definite atrophic changes may sometimes be seen in the intestinal mucosa. In order to compare periods in the life of a rat with periods in the life of man it is necessary to multiply the former by about 20 times. Donaldson, in his book on the rat, gives an even higher figure (30 times). The length of life of a rat is three to four years and it is sexually mature after five to six months. The first four weeks in the life of a rat correspond therefore to the first two or three years in the life of a child. And underfeeding practised in a stock of rats for three years involves four to five generations.

MODE OF ACTION OF VITAMINS.

The significance of these observations is bound up with the problem of the mode of action of vitamins. The first investigators of the conditions produced by the complete absence of vitamins noticed no specific pathological lesions, and believed that the decline in health of the animal was due to a general decline of all its cells. The generalisation was formulated that all cells require a small amount of vitamins for their life and growth. If this amount is supplied the animal is held to be in normal health and to store

[4] THE LANCET, 1923, i., 1046.

the excess in its tissues. If less than the required amount of vitamins is supplied the health of the animal declines unless it has a store of vitamins in its tissues on which it is supposed it can draw. As already stated, the vitamins are supposed to have no positive physiological action of their own. The organism is regarded as a test-tube in which the cells of the organism are titrated against vitamins. If the quantitative relationship between these two reaches a certain proportion we have growth and health; if it falls below that—no growth and disease.

I have repeatedly criticised this view and pointed out that this conception is based on assumptions which do not agree with observed facts. Isolated cells can grow and live without vitamins, although a highly differentiated organism as a whole cannot. Vitamins have a positive physiological action corresponding to the action of hormones. There are specific pathological lesions produced when vitamins are withheld from the food, and these lesions account for the onset of the specific deficiency disease.

To take the last point first. In the absence of vitamin B there is invariably an anatomical and functional atrophy of the lymphoid tissue throughout the body, which is reflected in the circulating blood by a lymphopenia. In the absence of vitamin A there is an atrophy of the intestinal mucous membrane. There is a similar atrophy of one of the paraocular glands and also a great reduction in the number of blood platelets. Dr. R. G. Bannerman has informed me that he has been able to confirm this thrombopenia in rats kept on a diet free from vitamin A. These lesions account for the specific diseases produced by the absence of the two vitamins. If the atrophy of the lymphoid tissue is produced by some agency other than the deficiency of vitamin B, for instance, by exposure to radium, we get the same condition of marasmus that is characteristic of vitamin-B deficiency. In a paper published by Drew, Mottram, and myself in 1921, entitled "On the Function of the Lymphocyte and of Lymphoid Tissue in Nutrition," it was pointed out [5] that human pathology furnishes further evidence in support of the intimate relation of the lymphoid tissue to nutrition. The blood of infants and children contains four to five times the number of lymphocytes present in the blood of the adult. Disturbances of the adenoid tissue are of special significance in childhood and are known to be frequently associated with disturbances in nutrition. There are in infants extreme disturbances of nutrition which cannot be ascribed to neglect or deficient feeding. In such cases of marasmus, atrophy of the lymphoid tissue —thymus, spleen, Peyer's patches—are the main lesions found. An important function of the lymphoid tissue is, therefore, to maintain the nutrition of the body—a view which is also held by the French physiologist, Jolly, on similar grounds. An interesting confirmation of this view has been adduced quite recently by Carrel,[6] who, I regret to say, has not seen fit to acknowledge our work, from his observations on the cultivation of fibroblasts in vitro. He finds that these cells can only grow in serum when lymphocytes are added to it and argues from this that the lymphocytes synthetise from the serum substances necessary for growth. The condition produced by vitamin A deficiency is less well defined; it may be described as a condition beginning with vague ill-health and malnutrition which finally culminates in the onset of bacterial infections of an avirulent type affecting especially the eyes and the lymph glands in the neck. Frequently there is also an anæmia. A glance at Fig. 1, which represents two villi in the lower end of the small intestine stained for bacteria by Murray's Nile blue–Van Gieson method, shows how such a condition arises as the result of the pathological changes in the intestinal mucous membrane. The villi are not only atrophic as shown in figures published in a previous paper and have in part lost their epithelial covering, but the bacteria which in a normal animal are confined to the centre of the lumen of the intestine penetrate down between the villi and into the remotest recesses of the Lieberkühn's crypts. The mucous glands of the cæcum present a similar penetration by bacteria. A similar condition is produced by exposure to radium, as Mottram has shown. The effect of radium is established more rapidly and by following the changes Mottram [7] has been able to show that the primary effect is on the secretion of mucus at first. The mucin secreting cells increase in number and this is followed by atrophy. A similar change is visible in the intestinal mucous membrane of rats kept on diet free from the fat-soluble vitamin, but owing to the more chronic nature of the change, which may extend over several months, the sequence of this change is not so clear. In some parts the number of mucous cells is increased, but the cells are large and empty, with a wide opening towards the intestinal lumen. Bacteria may sometimes be seen in the empty vacuole. In other parts there may be a remarkable absence of mucin secreting cells. In a previous paper [8] I have given the figure of a mucous gland of the cæcum distended with bacteria. Reference to that figure will show a complete absence of mucous secreting cells. The necrotic and atrophic changes affecting the villi and the invasion of bacteria are probably the result of this primary effect on the secretion of mucus which has a protective action. The typical eye infection which is the most obvious sign of vitamin A deficiency can be explained in the same way. For Yudkin and Lambert have demonstrated profound atrophic changes in one of the paraocular glands—the Harderian gland. This gland resembles a mucous gland and has been described as such. These specific atrophic conditions disappear quickly when the specific vitamins are fed to the animals. Thus vitamin B stimulates the lymphoid tissue which rapidly regains its volume and functional activity so that the number of lymphocytes increases in the blood. Similarly the atrophy of the intestinal mucous membrane disappears when vitamin A is given, the blood-platelets rapidly increase, and the infections disappear.

This is in itself indication of a positive stimulating effect of the vitamins. But such an effect can be demonstrated not only in animals suffering from a vitamin deficiency but also in perfectly normal animals. Mottram, Drew, and I have shown that the absorption of food as indicated by the absorption of fat is greatly affected by the presence of vitamins. And Uhlmann, Voegtlin and Myers, Drummond and Anrep found that extracts of certain foods rich in vitamins when injected into the blood stimulate the pancreas to secrete. It is curious that this very significant fact has not received the attention which it deserves, presumably because it did not fit in with the current conception of the mode of action of vitamins. Another fact of considerable practical interest is the powerful stimulating effect on the appetite exerted by vitamin B, so that when this vitamin is absent from the food the appetite at once falls. All these observations taken together lead naturally to the conclusion that *vitamins are hormone-like substances present in the food.* They have a specific stimulating action on certain tissues, and these tissues themselves are dependent for their normal functional activity on the continued stimulation by these substances, in the same way as, for instance, the uterus is dependent on the ovarian hormone. We may describe, therefore, the vitamins as "food hormones," or "trophacoids," if we adopt Schäfer's nomenclature of calling the internal secretions "autacoids." And if we recall what tissues are dependent in this way on a continued extraneous supply of hormones in the food we find that they are mainly, though not exclusively, those which are concerned with the digestion, absorption, and assimilation of food—a very natural relationship.

[5] THE LANCET, 1921, ii., 1202.
[6] Journal Exper. Medicine, 1923, xxxviii., 513.
[7] Proc. Roy. Soc. of Medicine, Section of Electrotherapeutics, 1923, xvi.
[8] THE LANCET, 1923, i., 1046.

It is a very curious fact, too, that many of the tissues which are thus particularly sensitive to the extraneous agency of food hormones are sensitive also to another and quite different extraneous agency —namely, radiation. Exposure to radium will produce the same atrophic lesions and the same general effects as a deficiency in vitamins. Very small doses of these radiations produce a stimulating effect and there is an increase in the number of both lymphocytes and platelets. Another kind of radiation, light, has also a stimulating effect on the platelets and this may be the explanation of the curious fact that exposure to ultra-violet light delays the decline of an animal kept on a diet free from vitamin A. It has been said that it is difficult to understand on biochemical grounds how a physical agent such as light can take the place of an article of diet. It is, indeed, difficult, if we look upon a living highly differentiated organism as a test-tube in which quantitative chemical relationships exist between the cells and vitamins; and the only explanation which has been given on the basis of the chemical conception is that rats that receive light use vitamin A more economically. But from the biological point of view there is no difficulty in understanding that different stimuli —chemical, mechanical, electrical — when applied to living protoplasm produce the same effect. Light, however, does not have a stimulating effect on the intestinal epithelium or on the paraocular glands—at least in the doses which we have applied — and therefore the atrophic changes in these tissues due to the absence of the fat-soluble food hormone are not counteracted. It is interesting to remember that vitamin A is formed by plants in the presence of light. The more highly differentiated forms of animal life are not dependent for the maintenance of their functions on light to the same extent as plants, although light is still capable of stimulating the functional activities of some of their cells. The higher forms of animal life have instead become dependent for their well-being on the supply of a chemical substance for the formation of which light is necessary.

FIG. 1.

Lower end of small intestine of rat kept on a vitamin A free diet for seven weeks when the eye affection supervened. The animal was killed. Formol saline × 440. Stained with Nile blue–Van Gieson for bacteria. The bacteria have penetrated between the villi and into the Lieberkühn crypts. Note also the peculiar condition of the mucous cells.

THERAPEUTIC APPLICATION OF VITAMINS.

The significance of the conception of vitamins as food hormones from the point of view of evolution is obvious. Of more immediate practical application is the consideration that the need for these food hormones is greatest immediately after birth and in the first few years of life when the organism is adapting itself to a new environment and when the tissues which are stimulated functionally by the food hormones assume their functions. It is obvious also that this conception has a therapeutic application not confined to the deficiency diseases. We possess in these food hormones valuable drugs with a specific action. As a matter of fact, yeast had been used empirically, long before the existence of vitamins was known, as a remedy for two minor complaints, boils and constipation. Quite recently the use of yeast as a remedy for constipation has again been tested very carefully by Murlin,[9] and its value has been confirmed, and Gross has demonstrated the same for marmite, a yeast preparation rich in the water-soluble B.[10] We have seen that this food hormone stimulates the lymphoid tissue and this is probably the explanation of its usefulness in furunculosis. We have also seen that it affects favourably the processes of digestion and absorption in the intestinal canal, which would account for its use in relieving constipation. The constipating effect of the absence of vitamin B seems to be due to retention of the fæces in the large intestine and not to a general intestinal stasis, as has been stated, for unpublished observations by Dr. Mottram and myself showed that the passage of food through the small intestine is not delayed if vitamin B is absent. A direct result of this conception of food hormones has been the revival of their therapeutic application in certain forms of marasmus in infants not due to neglect or deficient feeding and therefore not due to a deficiency in vitamins. The functional atrophy of the lymphoid tissue and of the intestine, which is found post mortem in such cases, must therefore be regarded as a primary cause. It can be remedied by the active stimulation of these tissues by means of preparations richer in vitamins than milk. In practice it has been found that many cases of marasmus which have proved resistant to treatment by most careful feeding improve rapidly after the administration of cod-liver oil, malt, and orange juice. This is, in fact, an old empirical treatment which had fallen into disuse and which, during the last two years, has been applied again extensively. I am indebted for this information to Dr. D. Paterson, of the Hospital for Sick Children, Great Ormond-street.

[9] American Jour. of Physiology, 1923, lxiv.
[10] Journal of Pathology and Bacteriology, 1924, xxvii., 27.

From this conception of vitamins as food hormones it follows that their therapeutic application is not confined to the conditions which are caused by a deficiency in vitamins. Conversely, the fact that a vitamin relieves a disease does not necessarily prove that the disease was due to the deficiency in this particular vitamin. This consideration may help to clear up some difficulties and contradictions which have arisen. Thus the fact that cod-liver oil cures rickets does not necessarily prove that rickets is caused by a deficiency in any particular factor present in cod-liver oil. As a further example of the therapeutic value of these food hormones, the clinical observations by Hawk, Knowles, Rehfuss, and Clarke [11] may be mentioned. They studied the effect of a yeast preparation on a great number of different conditions such as furunculosis, acne, constipation, gastro-intestinal catarrh, &c. Seventy-six cases were treated, 66 improved or were cured, and apart from the improvement in the symptoms there was also a general improvement.

The therapeutic value of the fat-soluble food hormone is, of course, exemplified by the powerful therapeutic effect of cod-liver oil in a variety of different affections, especially infective conditions of a chronic kind such as tuberculosis. It may be that in these conditions this effect is partly related to its stimulating action in the formation of platelets. A good deal of experimental evidence, for which reference must be made to our previous papers, has accumulated recently which indicates that the platelets are a mechanism of defence against certain types of bacterial infections. It is suggestive that the two useful remedies in tuberculosis—cod-liver oil and light—both increase the number of platelets.[12]

But the most important therapeutic action of the fat-soluble trophacoid lies in its action on the intestinal mucous membrane. In a normally functioning intestine the bacterial and protozoal flora is confined to the centre of the intestine owing to the protective action of the mucus. Mr. C. J. Bond [13] has recently expressed the view based on experimental observations that mucus may play a biochemical as well as a mechanical part in the protection of mucous membranes against infection. When the normal functioning of the mucous secreting cells is impaired by a deficiency of vitamin A in the diet the bacteria and protozoa can be seen to attach themselves to the surface of the villi, to creep down between the villi into the crypts, and even into the atrophic mucous cells, and to proliferate there. In a previous paper I have given a drawing of a mucous gland of the cæcum distended with a mass of bacteria, and no mucous secreting cells are visible in that section. Cestodes also are present much more frequently in the intestine of rats kept on vitamin-deficient diets. As a rule, these bacteria and protozoa are of an avirulent type, and so the animal quickly recovers when vitamin A is administered in the form of cod-liver oil. But if the organism should be the carrier of a virulent bacterial or protozoal organism, then the conditions for an outbreak of a virulent specific infection are given. A very important experiment of this kind, carried out with monkeys, has been recorded by McCarrison,[14] who has also emphasised the importance of vitamins in the ætiology of gastro-intestinal disorders generally. The action of the fat-soluble food hormone on the mucous glands enables the intestine to keep in check its pathogenic inhabitants and thus confers protection against intestinal disease. And what applies to the intestine applies with equal force to the eyes. It is surely a suggestive fact that the two chief seats of disease in tropical countries, where the consumption of those articles of diet rich in vitamin A is necessarily restricted, are the eyes and the intestine.

[11] Journal American Medical Association, 1917, lxix., 1243.
[12] A striking clinical example of such a relationship has been published recently by R. G. Bannerman, Brit. Jour. Exp. Path., 1924, v., 16.

[14] THE LANCET, 1922, i., 208.

PROBABLE VITAMIN UNDERFEEDING OF THE POORER CLASSES.

And now I come to what I believe is the most important aspect of vitamin dietetics. If we compare these apparently healthy but under-sized rats of litter B, in which out of six rats two rats kept in separate cages died from lung infections when they were only a few weeks old, with the big, well-developed animals of litter A, all of which survived, if we remember that both litters received the same basal diet and that the only difference was that the animals of litter A came from a stock which had received through several generations an additional supply of vitamins in the form of a yeast preparation and of cod-liver oil—and if we then consider the large number of under-sized, ill-developed children and adults that we can see any day in the streets of any big town, the question is forced upon us: Is this vitamin underfeeding—of which litter B is an example, and which has been going on in our laboratories quite unintentionally for many years, without any gross evidence of disease—going on on a large scale in our population? The main articles of diet for the poorer classes are bread, margarine and jam, meat and potatoes, and for the smaller children milk. The main supply of the water-soluble food hormone B ought to be bread, since whole-meal flour is abundant in this vitamin. But the white bread of to-day is poor in this vitamin, because as the result of the fine milling those parts of the wheat grain that contain this vitamin are eliminated. Bread used to be called "the staff of life," but that was a long time ago when whole-meal bread was used. Our bread of to-day had better be called "a broken reed." In the diet mentioned, potatoes are practically the only source of vitamin B—and they are not rich in this substance. The substitution of margarine for butter deprives us of the main supply of vitamin A. Many brands of margarine are completely free from this vitamin, some contain a small amount of vitamin A, but not as much as butter. There remains only milk as the remaining source of vitamins provided that whole milk is given and not milk that has been deprived partly or entirely of its fat, and thereby of vitamin A. And the boiling of the milk, which is rendered necessary in the present unsatisfactory state of the milk-supply in big towns, further reduces the amount of vitamins that may be present. It will be remembered that on a very similar diet in a Danish institution the outbreak of keratomalacia occurred which Bloch investigated. The well-to-do classes make up for this by a consumption of eggs, butter, green vegetables and salads, and fruit, all of which are rich in vitamins. I do not see how it can be denied that under present conditions of town life large classes of the population live on a diet which contains only a small fraction of the food hormones present in the food in its natural state. This defect in our diet has also been pointed out by McCarrison, and in America by Osborne. The prevalence of constipation is a good indicator of an underfeeding of the water-soluble food hormone. It was recognised long before we knew anything about vitamins that the use of white bread was responsible for constipation, and that the latter disappeared with the substitution of whole-meal bread for white bread. It was then believed that the presence of indigestible cellulose material in brown bread acted as a mechanical stimulus to the intestine. But since this constipation can also be remedied by giving vitamin B in the form of yeast, the cause of the constipation must be sought in underfeeding with vitamin B, and not in the absence of a mechanical stimulus. If we consider that bread ought to be the main supply of vitamin B in the diet it is startling to remember that an outbreak of beri-beri occurred among the British troops in Mesopotamia when they were living on rations of white bread and tinned meat.

We have seen that certain tissues or groups of cells are dependent for their full functional activity on the continued stimulation by the food hormones, that their activity declines as we diminish the supply of

these food hormones until we get atrophy with the prolonged complete absence of food hormones. There is no hard-and-fast line where disease begins and health ends, but a whole series of gradations of functional activity. The so-called deficiency diseases in their typical form represent merely the extreme end of this series. The intermediate stages of chronic vitamin underfeeding may manifest themselves only in a young organism by less rapid growth or not at all until the occurrence of incidental disease superimposes a new strain upon the organism. Thus, in our vitamin-underfed rats the lymphoid tissue and the intestinal mucosa are not as well developed as in the rats from the vitamin-rich stock; in fact, the intestinal mucosa frequently shows atrophic changes approaching those seen in vitamin A deficiency, and spontaneous lung affections are much more frequent than in the vitamin-rich stock. This difference refers to underfeeding in vitamin A and B, since rats are not dependent on a supply of vitamin C. Marshall Findlay[15] has induced a condition of "latent scurvy" in guinea-pigs by underfeeding them with vitamin C. Such animals present, like our rats, no obvious external signs of ill-health. Histological examination shows, however, that the blood-forming bone-marrow is atrophic, and when these animals are experimentally infected with pathogenic bacteria it is found that their resistance to such infection is greatly diminished. Some interesting clinical evidence bearing on this point has been recorded by Hess, of New York,[16] whose work on rickets is so well known. He observed in 1913 in a group of children which had been fed on pasteurised milk a widespread grippe infection with hæmorrhagic skin manifestations. He attributed this to a "scorbutic taint" in these children, and brought about a disappearance of these skin manifestations by the administration of orange juice. Hess also draws attention to the frequent coincidence of nasal diphtheria and what he calls "latent" scurvy. When a large number of cases of nasal diphtheria develop, suspicion should be aroused that the infection is implanted in tissues weakened by scorbutic or other nutritional disorders. He also quotes Davidsohn, who attributes the spread of tuberculosis in Central Europe during the war to a defective supply of vitamins.

Many clinicians have been sceptical about the importance of vitamins in the ætiology of disease, because typical deficiency diseases as they are induced in the laboratory experiments by complete deficiency of vitamins are a rare occurrence in our population though, as we have seen, they do occur), and because the complete absence of one or other vitamin from the food of people living on a mixed diet can only occur in exceptional circumstances. But what the clinicians are likely to meet with, according to the conception which I have laid before you, are the results not of an acute complete vitamin deficiency but of chronic vitamin underfeeding. On this point Hess's views are most instructive. From his clinical experience he urges clinicians to realise that—

> The harmful effects of food deficiencies should not be associated in our minds essentially or chiefly with specific diseases such as scurvy or rickets, but rather as disorders of nutrition, producing slight and manifold disturbances of function. It is probable that every organ or system in the body may be affected by faulty nutrition. For example, involvement of the eyes may lead to impaired vision or nightblindness; or, on the other hand, neuritis, cardiac enlargement, disturbances of the circulating system, atrophic disorders of the skin, nails or hair, caries of the teeth, or unaccountable lack of appetite and constipation may each in turn be the earliest symptom. A more careful inquiry into the dietary of patients will result in bringing to light many cases in which vague and ill-defined symptoms can be remedied simply by rendering the diet adequate."[17]

Before I conclude I wish to revert once more to an important point. It is the infant and the child and therefore also the pregnant and nursing mother who is particularly in need of an abundant supply of these food hormones. Experimentally, it is a well-established fact that the younger the animal the more rapidly does it succumb to a deficiency in vitamins. Clinically, the most obvious and typical results of vitamin deficiencies have been observed in children, and you will have noticed that most of the clinical evidence which I have presented to you refers to children. From our conception of the vitamins as food hormones it is easy to understand why that should be so. The alimentary canal does not begin its function until birth, and we know that it is a most vulnerable part of the infant's organism. Its functional development is moulded, so to speak, by the stimulation it receives through the food hormones. If their supply is restricted, the functional development will be impaired, and a lasting damage may be inflicted which cannot be made good by an ample supply of vitamins in later life.

That is the pessimistic view. But the optimist may point out in reply: If care is taken to ensure an abundant supply of vitamins to the pregnant and nursing mother and to the child in the first few years of its life a lasting benefit will be conferred upon the child. The intestine and the other tissues that are susceptible to the stimulus provided by the food hormones can thus and only thus attain their full functional activity. I do not wish to exaggerate the importance of vitamins. I do not wish to give the impression that they are a panacea for all ills, and that if we could only ensure an ample supply of vitamins to everybody we should all live happily ever after. It is, in fact, an essential part of my argument that the action of vitamins is not a vague general action on all cells, but an action circumscribed in the same sense that the action of a hormone is circumscribed. But I think the statement is justified that we have allowed our basal articles of food to be deprived of their vitamins, with the possible result that large classes of our population may be suffering from vitamin underfeeding, and living in the border-land between health and disease. If that is so, we are facing a big social problem. But, unlike many other problems of this kind, it is a problem scientifically circumscribed which will be remedied, as soon as its existence is generally recognised, by a demand for bread which contains an ample supply of vitamin B and for margarine with an ample supply of vitamin A, and by realising the importance of whole milk and the inadequacy of skimmed milk in the feeding of children.

EXPERIMENTS IN NOURISHMENT OF CHILDREN.

How big this problem is, to what extent of vitamin underfeeding our population is subjected, can only be determined by experiments on man on a large scale. An experiment of this kind has already been carried out in America in some of the board schools in Chicago, and has been reported on by Dr. Katharine Rich.[18] The experiment was carried out because the startling discovery was made that 53 per cent. of the children of 14 applying for employment certificates were from 7 per cent. to 21 per cent. below the average child of that age and when employed could not carry out their usual amount of work. This defective condition was found to be due to faulty nourishment and was remedied mainly by correcting the diet. By ensuring the consumption of an ample amount of milk, and by instruction on the value of personal hygiene and cleanliness, an average gain was recorded within less than a year of 121 per cent. in weight and 64 per cent. in height in excess of the usual gain. These observations, which were made on 500 children, were not expressly designed to test whether the defective physical condition of these children was due specifically to vitamin underfeeding. There may have been other dietetic errors which were also corrected by the increased consumption of milk. For the distribution of food hormones in the basal articles of

[15] Journal of Pathology and Bacteriology, 1923, xxvi., 1.
[16] Journal American Medical Association, 1921, lxxvi., 693.
[17] Ibid.
[18] Journal American Medical Association, 1920, lxxv., 226, 1492; 1921, lxxvi., 998.

our diet is such that a deficiency in vitamin is usually accompanied by other deficiencies. Milk is particularly rich in calcium salts, and margarine is poor not only in vitamins but also in calcium salts as compared with butter. It may, in fact, be taken as a practical guide that if a diet composed of natural basal articles of food contains an ample supply of vitamins it is correct also in other respects. It should always be remembered that to correct the deficiency of our diet in food hormones by the addition of cod-liver oil for the fat-soluble A and malt or a yeast preparation such as marmite for the water-soluble B is only a makeshift.

The great value of the Chicago experiment, in which the dietetic faults were corrected not by a free supply of milk but merely by instruction and supervision, consists in having shown that such an experiment is practicable, inexpensive, and successful beyond expectation. From what has been pointed out in this paper, it would be even better to begin with the beginning, and in selected groups of families who are at present living in a condition of vitamin underfeeding to carry out an experiment of this kind on the pregnant and nursing mothers and on the children in the first years of life.

A COMMUNICATION BETWEEN THE VAGUS AND THE CERVICAL SYMPATHETIC,

WITH ITS CLINICAL ASPECTS.

BY R. C. SHAWE, M.R.C.S.,
SURGICAL REGISTRAR, ROYAL INFIRMARY, MANCHESTER.

THE recent operations performed by Jonnesco for the treatment of angina pectoris, in which he extirpates the middle and inferior cervical sympathetic ganglia, directs attention to the anatomical communications of these structures. It is the primary object of this paper to describe some of these connexions which pass between the inferior and middle cervical sympathetic ganglia and the vagus nerve with its branch, the recurrent laryngeal—including their detailed distribution, which appear to have hitherto escaped particular notice—and secondarily to draw attention to the clinical aspects of these associations.

Anatomy.

Examination of the connexions of the inferior cervical ganglion on various occasions showed that a direct nervous link was frequently present between the right vagus and this structure, and in addition there was sometimes seen to be a communication between the middle cervical ganglion and the vagus. In the literature dealing with these parts no mention is made of any such direct link between vagus and sympathetic, although Cunningham describes the connexion between the recurrent laryngeal and the third cervical ganglion. Swan's work on the "Nerves of the Human Body" contains a plate illustrating a nerve joining the right vagus below the origin of the recurrent laryngeal, which appears to arise from the loop between the second and third cervical ganglia, but he gives no description of it. Twenty-five bodies, including three fœtuses, were examined for communications between the vagus and inferior cervical ganglion, which resulted in its presence being confirmed in 14 of the adult bodies, and in all three fœtuses—that is, in 68 per cent. of the specimens investigated. With regard to this percentage, it must be mentioned that the adult bodies were being dissected by students, which necessitated waiting for the removal of the lungs and the deep dissection of the neck before one could examine the region in question, a factor which might contribute to the number of negative instances, since this communication is almost invariably torn away if the mediastinal pleura near the apex be roughly removed. In this respect it is noteworthy that it was found in all three fœtuses.

The Relations of Vagus and Cervical Sympathetic.

The nerve passes from the inferior cervical sympathetic ganglion downwards, inwards and forwards to the right vagus just below the point where that nerve crosses the first part of the right subclavian artery; it is therefore lying in a very oblique plane in relation to the inner side of the pulmonary apex, amidst the subpleural connective tissue. At its sympathetic extremity it is closely related to the brachial division of the first dorsal nerve and the first rib; passing downwards beneath the subclavian artery it is in juxtaposition to the loop between the inferior and middle cervical ganglia. Close to its inner side is the branch from the inferior cervical ganglion to the deep cardiac plexus, and often several sympathetic filaments to the œsophagus and trachea. The general anatomical relations of this nerve will be seen in Fig. 1, which shows one of the fœtal dissections.

FIG. 1.

General anatomical relations of cervical sympathetic, from a fœtal dissection. The vagus, the sympathetic, and the communicating nerve are painted white; the nails are inserted in the severed ends of the right common carotid and right subclavian arteries respectively. The phrenic nerve is seen crossing the pericardial sac. The recurrent laryngeal passed inwards in contact with the under-surface of the subclavian artery at the point of junction of the communicating branch with the vagus; consequently it is not shown.

Preliminary to describing the detailed connexions of the vagal extremity, it is opportune to mention the method by which these were traced. The vagus and sympathetic and their communication in this region were removed en masse, and dissected under water with the aid of a lens; in this way it was easy to trace the largest fasciculi, and possible to follow them still further with the aid of transmitted light, dissecting across the aperture of a shaded electric lantern. The application of a fat solvent was also found to be useful; for this purpose benzine was swabbed over the fibres, which freed them from adherent fatty tissue, revealing the sharp outline of the nerve.

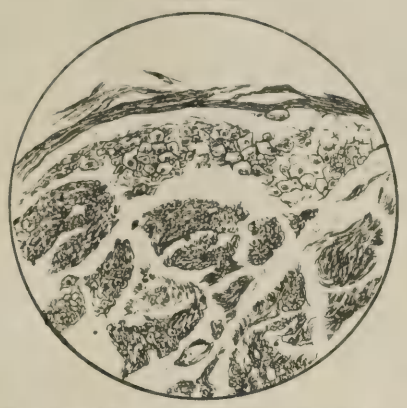
In describing the detailed connexions of this vago-sympathetic communication, it will be advisable to consider the two sides separately on account of the difference presented; further, it may here be remarked that although the communication to be most particularly described passes from the inferior cervical sympathetic ganglion, there was noted in several of the specimens examined a similar link with the vagus proceeding from the middle cervical sympathetic ganglion; the connexion of the former nerve will be detailed first on the right side.

Sympathetic Extremity.—The origin of this communicating nerve from the inferior cervical ganglion was generally found to consist of two small branches, given off from the ventral surface of the ganglion, which immediately united to form the nervous link. Though this description is generally applicable, a

variation in the mode of origin was observed. In two of the specimens examined the nerve had an additional root from the cervical sympathetic chain which separated from that structure at a distance of about one inch above the inferior cervical ganglion; there were also the usual two roots from the latter which, after uniting, passed forward to join the third root and form the characteristic vagal connexion.

Vagal Extremity.—This end of the nerve usually presents a scheme of subdivision that may be accepted as characteristic of the structure—namely, a Y-shaped division—one portion passing downwards to the vagus, and the other entering the recurrent laryngeal a few millimetres from where the latter leaves the vagus. As a variation of this almost constant distribution, it was occasionally noted that the communicating nerve proceeded to the precise point of origin of the recurrent laryngeal, in which case the Y division was absent, whilst in one specimen the nerve joined the recurrent laryngeal about one inch from the origin of the latter from the vagus.

FIG. 2.



Drawing from microphotograph, showing large medullated fibres principally concentrated in a small bundle on the periphery of the nerve, a few being also scattered about the bundles.

Distribution.—This may be most readily followed with the aid of the diagrammatic representation (Fig. 5). Here the inferior of the two main divisions entered the lower border of the vagus, wherein many of its fibres could be traced as far as the branches to the deep cardiac plexus. The other principal division entered the recurrent laryngeal a few millimetres from its commencement. Herein it underwent a distribution such that the part proceeded peripherally (*e*) in the recurrent nerve; the remainder ascended to the vagus and divided into ascending and descending branches. The latter (*g*) could be distinctly traced into the centre of the vagus, which point is emphasised to show that the fibres are not merely adherent to the surface of that nerve, but definitely incorporated therein, a fact which was also definitely shown by histological examination, to be referred to later. These caudal fibres were traceable as far as the plexus gulæ, but no filaments appeared to emanate in the direction of the cardiac or pulmonary plexus. The cranially directed division also passed into the interior of the vagus, but was lost after tracing it about one inch, the fibres becoming intimately intermingled with those of the vagus. As a slight variation to this distribution the specimens which showed a three-fold sympathetic origin on approaching the recurrent laryngeal about an inch from the latter's origin, gave an accession of fibres to that nerve by a separate branch, the fibres of which passed in a peripheral direction. It then adhered to the recurrent nerve, many of its remaining fibres passing on in a distinct cardiac branch, while the others appeared to decussate with the recurrent fibres and ascend to the vagus.

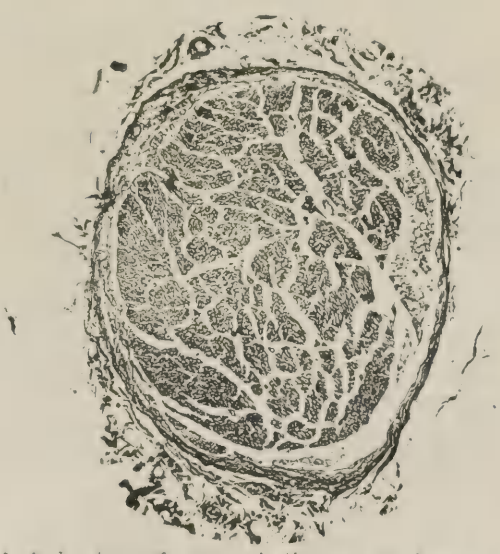
Left Side of the Body.—The anatomical connexions between the vagus and the sympathetic differ somewhat from those above described; in only one of the dissections was there any trace of a direct vago-sympathetic connexion, and this was in a fœtus. In this sole occurrence the distribution was precisely similar to that found on the right side; the branch from the inferior cervical ganglion having the same dual origin, and was distributed on reaching the vagus in the characteristic Y-shaped manner, some of the fibres ascending and others descending, the only exception being the absence of a branch to the recurrent laryngeal. In many of the remaining specimens examined the place of the communicating branch would appear to be taken by several large fasciculi, which passed from the third cervical ganglion to join the recurrent laryngeal. This arrangement was met with in ten adult bodies examined, but in six others the branches from the inferior cervical ganglion were found to pass independently to the deep cardiac plexus.

Distribution of Branches.—Dissections of these recurrent sympathetic communicating nerves demonstrated that on joining the laryngeal nerve their fibres are distributed in both directions, some

FIG. 3.

Funicular type of communicating nerve surrounded by loose connective tissue, containing small blood-vessels, which form the epineural sheath; internal to this is the nerve proper, subdivided into funicular bundles, each surrounded by a definite perineural sheath of fibrous tissue.

FIG. 4.

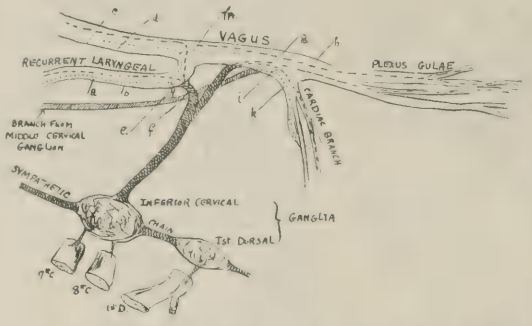


Non-funicular type of communicating nerve, showing loose epineural tissue surrounding a single perineural sheath, enclosing the entire nerve, the fibres of which are segregated into bundles, only separated by a very scanty endoneural tissue.

ascending towards the larynx; others descending in this nerve appeared to leave it mainly by several branches to the aortic and deep cardiac plexus, at the point where the recurrent laryngeal passes behind the arch of the aorta in close relationship with the commencement of the left bronchus (Fig. 6). The descending fibres are shown by the interrupted line *a*; it was thought that in the specimens dissected some of the fibres continued beyond the origin of the cardio-aortic branches to ascend to the vagus trunk, but with regard to this point one cannot speak with certainty, although such a distribution is to be expected from the analogy of the right side and from comparison with the one example of a direct vago-sympathetic link on the left side. The presumed course of such fibres is into the deep cardiac branches of the vagus, whilst others appeared to be merely adherent to that nerve and to separate from it with the cardiac filaments. On the left side of the body this middle cervico-vagal communication was also represented. It was present both in the dissection which revealed the direct vago-sympathetic link, and in those where the connexion was established with the recurrent laryngeal. This nerve was quite independent of the middle cardiac branch from the ganglion, and as shown in Fig. 6 by the line H.

Distribution on Left Side.—A closer examination proved this to follow the usual bifurcate arrangement, branches both ascending and descending in the recurrent laryngeal.

FIG. 5.



(*a*) Fibres from middle cervical communication passing peripherally in the recurrent nerve. (*b*) Fibres from inferior cervical communication passing in same direction as above. (*c*) Fibres ascending in vagus from inferior communication. (*d*) The same from the middle communication. (*e*) Branch of middle cervical link to the recurrent laryngeal. (*f*) Branch of same to vagus. (*g*) Fibres from inferior communication descending the vagus. (*h*) Thoracic cardiac branches of vagus. (*i*) Fibres from inferior communication passing into cardiac branches of vagus. (*k*) Same from the middle communication. (*m*) Fibres descending in the vagus from the middle and inferior communications via the recurrent nerve.

(*h*) Middle cervico-laryngeal communication.

shown by the line *d*. H is the middle cervico-laryngeal communication quite independent of the middle cardiac branch from the ganglion.

Middle Cervical Ganglionic Branch.

Besides these connexions between the inferior cervical ganglion and the vagus the presence of another sympathetic link with that nerve from the middle cervical ganglion was noted in several instances. Following the previous plan, the right side may be described first. The nerve was observed in eight of the 25 specimens examined. Its general relations are practically those of the communication just described, running obliquely downwards, inwards, and slightly forwards beneath the first part of the right subclavian artery in close relationship with its vertebral branch, the vagal link with the inferior ganglion, and also with the annulus of Vieussens.

Vagal Connexions.—This nerve was seen either to join the recurrent laryngeal or to divide, one portion going to the last-named nerve, the remainder to the vagus.

Intraneural Distribution.—The details of the distribution of these branches within the vagus and recurrent laryngeal will be more readily appreciated from a study of the diagram (Fig. 5), where the detailed connexions will be observed to be very similar to those of the branch from the inferior ganglion. The twig to the recurrent laryngeal (*e*) divides on entering that nerve, one portion of the fibres passing in a peripheral direction, the remainder are centripetal in their course. The latter on reaching the vagus subdivide into cranial and caudal divisions (*d* and *m*). This manner of distribution was found in both types above mentioned, although as an addition in the second type the principal accession of fibres was to the vagus below the junction of the inferior cervical ganglionic branch. These fibres (K) were traceable

Having discussed these vago-sympathetic communications from the purely anatomical aspect, one must attempt an elucidation of their physiological function in order to interpret their clinical significance.

Histology.

General Structure.—The general construction of this nerve in man appears to follow two definite formations depending on the presence or absence of funiculi; the usual construction is the funicular type seen in most nerves (see Fig. 3). In contrast to this formation is the appearance presented by the non-funicular type (see Fig. 4), where the loose epineural tissue surrounds a single perineural sheath enclosing the entire nerve, the fibres of which are segregated into bundles, only separated by a very scanty endoneural tissue.

Detailed Structure.—Turning to the detailed structure, the non-funicular nerve contained the two general types of fibres, the myelinated and non-myelinated; although there are many small groups of the latter type evenly distributed throughout the bundle, there appeared to be a general preponderance of the myelinated type, which, according to their relative size, may be classified into three main groups. It should, however, be remembered that although the extremes of these groups are distinct from each other, there are intermediate sizes which render this classification very wide. The smallest type of myelinated fibres, as measured by a micrometer eyepiece, were from 1 to 3 μ in diameter; these are distributed generally over the funiculus, and are distinctly the most numerous of their class. They may be compared to the small vagal medullated fibres which convey inhibitory impulses, and in this respect, also, to the similar splanchnic fibres. The next in frequency are the medium-sized medullated fibres which vary in diameter from 6 to 8 μ; like the former they are evenly

distributed amongst the fasciculi. Lastly, there is the group of large medullated fibres which have a diameter between 10 and 13 μ; these are distinctly the least numerous of the constituent elements. In the specimen described they were principally concentrated in a small bundle on the periphery of the nerve (see Fig. 2), whilst a few were scattered about the bundles; in all about 25 of these largest fibres could be distinctly counted. In their size they may be compared to the large vagal and large sympathetic fibres described by Gaskell and Edgeworth, although the fibres classified as medium-sized in the present example would more strictly compare with the large fibres of these investigators, the largest fibre in the human specimens considerably exceeding them. They are likewise strictly comparable with the large afferent sympathetic fibres of Langley, which he associates with the capsular end-organs. In the funicular type the same general division of the constituent elements pertains, but with this distinct difference—that there is a great preponderance of the medium-sized medullated fibres averaging from 5 to 6 μ in diameter, comparing with Edgeworth's large sympathetic fibres. The small myelinated and non-myelinated types are relatively scanty, whilst the largest medullated fibres in this specimen averaged 7 to 10 μ in diameter, and although mainly present in a small funiculus were more generally distributed than in the previous example, in this case 24 fibres could be distinguished with certainty. A section across the cervical sympathetic chain above the inferior ganglion showed no presence of the largest medullated fibres, the majority of the myelinated fibres were of the small variety, measuring about 1 to 3 μ, although one or two were from 4 to 5 μ in size, the remainder being of the non-myelinated type.

Turning to the inferior cervical ganglion, a longitudinal section of that structure, passing through the origin of the vagal communication and the lower end of the cervical sympathetic chain, revealed an interesting feature; numerous ganglion cells can be seen in the origin of the latter, whilst the commencement of the vagal communication is devoid of this feature. It will be recalled that whereas the non-medullated fibres are the post-ganglionic axons of the cells in the lateral sympathetic chain, the medullated fibres, on the other hand, make no synaptic connexions in these ganglia; hence the significance of the nerve cells continuing into the cervical sympathetic chain, which contained many more non-myelinated fibres than the vagal communication, where the other variety predominate.

The course of these large sympathetic fibres was still further defined by examination of sections across the vagus above and below its junction with the vago-sympathetic communication. Above the connexion no medullated fibres in the vagus were found to exceed 5 to 7 μ in diameter, whereas after the accession of the sympathetic nerve large medullated fibres of 10 μ diameter make their appearance scattered about the vagus. In both localities many non-myelinated and small and medium myelinated fibres are present, the smaller size of the latter type averaging about 1 to 2 μ.

All of this evidence tends the more fully to show that the distribution of these largest medullated sympathetic fibres in man compares almost precisely with the course of the similar large fibres in the dog as described by Edgeworth—with this difference, that the human example exceeds the other in average size, although 10 to 12 μ fibres of a similar nature have been found in animals, as described by Langley.

We may therefore conclude that the inferior cervico-vagal communication mediates both afferent and efferent impulses, and that in respect to the former it transmits a specialised type of fibre, the large myelinated variety, probably mediating afferent impulses from capsular end-organs, which structures, according to the cases examined, must be situated in the visceral distribution of the vagus.

Clinical Aspects.

From the clinical side it would appear that the importance of these vago-sympathetic fibres depends upon their two main spheres of distribution: (1) To the cardio-aortic region, and (2) to the thyroid gland. In the former association they mediate, at least in some cases, as shown by the success of Jonnesco's operation, the critical nervous impulses of angina pectoris, transmitting the afferent stimuli from the heart and aorta, and very probably transmitting efferent stimuli to that region. These nerves form a concentration point for the sympathetic cardiac fibres from the upper dorsal segments, and as such present a readily accessible isthmus at which to attack the vicious cycle of irritation by surgical methods. In the latter association these same communicating nerves probably mediate secreting fibres to the thyroid, and it is the pathological hyper-excitability of such fibres which may form a most important ætiological factor in the production of exophthalmic goitre; consequently, in suitable cases, in association with the other cervical sympathetic ganglia, their extirpation would appear to be justified in this disease as judged by the results of Jonnesco's work.

In conclusion, I must express my thanks to Prof. J. S. B. Stopford for his helpful criticism and for facilitating the work in many ways.

THE MENTAL CONDITIONS FOUND IN CERTAIN SEXUAL OFFENDERS.

BY M. HAMBLIN SMITH, M.D. DURH.,
MEDICAL OFFICER OF H.M. PRISON, BIRMINGHAM, AND LECTURER AT BETHLEM ROYAL HOSPITAL, LONDON.

IN this paper I have endeavoured to indicate the mental conditions which may be discovered in the intensive study of cases of two kinds of "sexual" offence—namely, indecent exposure and indecent assault. All persons accused of either of these offences are closely studied when received at this prison. The results which are briefly described here are those obtained by the examination of a series of 100 cases (50 cases of either offence). The majority of these were studied before conviction, a point of great importance which will be referred to again. Every case of these offences received here during a period of about three years has been included in the series, with 26 exceptions. These exceptions comprised 15 cases of indecent exposure and 11 cases of indecent assault, in which the accused persons consistently protested their innocence, asserting either that there was a mistake in identification, or, in the cases of charges of indecent exposure, that there had been no improper intention, the usual explanation being that they were urinating in some more or less public place, under the impression that there was no one to observe them. I have, consequently, included in my series only those cases in which the accused man frankly admitted his guilt.

Some of the omitted cases were ultimately found not guilty. I do not wish, in the least degree, to suggest that the remainder of the omitted cases were improperly convicted. There was often overwhelming evidence that the explanation given by the offender was untrue. But it is to be remembered that in these, more perhaps than in any other offences, there is need to consider the psychology of the witness as well as that of the accused. This point is often overlooked. The evidence in these cases is often that of

children or young girls. It is not likely that deliberate perjury or false accusation is common. But quite apart from these conditions there is much need for caution. The degree of memory and the type of memory varies greatly in different persons. And all who have studied children psychologically are well aware of their high degree of susceptibility to the influence of suggestion, their vivid imagination, and their habit of believing in the reality of their fantasies. And the desire to create a sensation, and to take the centre of the stage, must not be forgotten, both of these conditions having a psychological explanation. All this indicates the necessity for consideration of the psychology of the witness. It is true that the law most properly requires some corroboration of the testimony of a child. But in this particular type of case the fact of having complained without delay to a parent or some other person is often taken as sufficient corroboration.

Consideration of Proven Cases Only.

While this question of the value of evidence in criminal trials is of great interest psychologically, and of great importance practically, we are not directly concerned with it here. My desire has been simply to present a series of cases in which there could be no possible doubt that we were dealing, in every instance, with an actual case of the offence charged. This point is of importance. In other published studies of series of offences of various kinds there has often been a considerable element of doubt on this head. The conditions found in the omitted cases were just as varied as those found in the cases included in the series. And had the statistics of the omitted cases been included, the percentages would not have been materially affected.

There are two main reasons for paying special attention to these particular offences. First, they form a fairly homogeneous group, and in this respect they differ from certain other offences—e.g., dishonesty—in which the accompanying circumstances may be of the most varied character. Secondly, there is general agreement that offences of the kind described in this paper are specially deserving of investigation. It is not always easy to persuade those who have not made a deep study of the subject that a case of larceny, for example, may appear, superficially, to be quite simple, and yet may be due to most obscure mental causative factors. But in the case of these "sexual" offenders there is a general feeling that we are dealing with something abnormal. As a consequence, courts of law are often much more willing to remand the accused person for purposes of examination before finally dealing with him.

Great Variety of Mental Conditions.

It is to the great variety of the mental conditions which may be found that I desire to call special attention. And the general results obtained by examination are set out in the following table:—

	Indecent exposure.	Indecent assault.	Total.
Insane	4	4	8
Mentally defective	11	15	26
Subnormal intelligence	2	2	4
Undeveloped physically and mentally	—	1	1
Senile degeneration	4	7	11
Epileptic	2	—	2
Mental conflict	18	13	31
Negative results	9	8	17
	50	50	100

The cases described as insane were, of course, all certified as such, and removed to mental hospitals. There were four cases of dementia præcox, two of senile dementia, and two of confusional insanity.

The cases of mental defect were all estimated by my special scheme of tests,[1] supplemented, in most instances, by the Terman scale applied by another examiner. There were six imbeciles, three in either group. Of the 26 cases of mental defect, 18 were certified under the Mental Deficiency Act, 1913, and removed to institutions for defectives. In two cases, although the mental defect was undoubted, there was difficulty in proving its existence "from an early age," as is required by the definition in the Act. This difficulty is now generally recognised as being a bar to the full usefulness of the Act. One of these latter cases was that of a man aged 63 years, who had 29 previous convictions for offences of this kind, but of whom it was impossible to obtain any history earlier than the age of 30 years. The remaining cases classed as mental defectives were placed under supervision, except in one instance, where the offender was rather oddly dealt with by being placed on probation.

The cases described as of subnormal intelligence were those in which there was some degree of mental defect, but in which this did not appear to be sufficiently marked to justify certification under the Mental Deficiency Act. What degree of mental defect should justify such certification is a matter for argument. But I am not prepared to accept the conventional rule, adopted in some quarters, which holds that the non-attainment of some particular "mental age," as determined by the Terman or other similar scale, should be the decisive factor in the question of certification. The expression "subnormal intelligence" is, of course, not wholly satisfactory, for certifiable defectives are themselves subnormal. But the group of subnormals is generally recognised, and the term was originally used by Healy.[2]

Before dealing with the other varieties of mental abnormality which were found, it will be convenient to give an age-table for the whole series of cases.

	Indecent exposure.	Indecent assault.	Total.
Under 21 years	6	16	22
21–30 years	25	16	41
31–40 ,,	11	3	14
41–50 ,,	3	1	4
51–60 ,,	1	2	3
Over 60 years	4	12	16
	50	50	100

In considering this age-table, it must be kept in mind that, under ordinary circumstances, boys under the age of 16 years cannot be sent to prison. The only case below that age in my series was that of a mentally defective boy of 15 years, who was remanded to prison under Section 102 (3) of the Children Act, 1908. The number of cases in each age-group is too small to allow of any sweeping conclusions being drawn. But it would appear that there is a tendency for these offences to increase in number up to the age of 30 years, after which there is a fall, followed by a marked rise after the age of 60 years. And having regard to the comparatively small number of men living after 60 years, the figures are striking.

Senile Degeneration.

The cases placed under the head of "senile degeneration" form a sad group, with which it is not easy to deal. In these cases there was evidence that senile mental decay was occurring, but that this had not attained to a degree which justified certification under the Lunacy Acts. That the present legal criteria of "criminal responsibility" require reconsideration is now generally admitted. It is a question whether this particular class of case does not furnish as grave, or even graver reasons for such reconsideration as any other. The recent legal committee, presided over by Lord Justice Atkin, has recommended that the law should be altered, and that a person charged criminally with an offence should be regarded as "irresponsible for his act when the act is committed under an impulse which the prisoner was in substance deprived of any power to resist." Without entering into the extremely complicated questions raised by this proposed extension of the present rules of law, it may well be that many of these cases could be brought within the limits of the proposed new ruling. Several of these cases in my series were those of men of hitherto irreproachable life. Two of the cases were placed under the supervision of their friends, and one was sent to a nursing home. The others were sentenced to terms of imprisonment of varying length

because there seemed to be no other way of dealing with them. But it must, surely, be admitted that this is an irrational way to treat such cases, even bearing in mind the paramount necessity for the protection of society. Much has been made, in this connexion, of the influence of irritation caused by chronic enlargement of the prostate gland. There is no doubt that many of these cases present symptoms of prostatic enlargement. But we must, I think, be cautious in accepting this as the "cause" of the offence, for in most cases we find definite mental symptoms in addition to the prostatic enlargement. Nor is the improvement which has been claimed, in some cases, as occurring after surgical treatment entirely convincing. The mental effect of the operation must not be overlooked. Nor may we forget that the fact of the patient assenting to the operation is some evidence of "insight," on his part, into his condition, and of desire for a cure. Krafft-Ebing [3] has suggested that these sex offences, committed by elderly men, indicate weakened sexual potency. May not the explanation, at least in some cases, be that the offence is the result of a mental conflict between unconscious desire and conscious knowledge of diminished potency? In this connexion we must remember the marked tendency shown by elderly men to marry quite young girls. For a full discussion of the whole question see Bresler,[4] and for statistics see Aschaffenburg.[5]

The marital condition of the men was as follows: Disregarding the cases under 21 years of age, all except one of whom were unmarried, of the exposure cases 55 per cent. were single or widowed, 45 per cent. being married, while for the assault cases the percentages were 71 and 29 respectively.

Mental Conflict.

The cases assigned to mental conflict form the largest and the most controversial group. In 11 of these cases the court was found willing to accept this explanation of the offence, and to place the man on probation, with the condition in some instances that he should receive proper mental treatment. To what extent, and with what results this condition was actually complied with, I am unable to say. And this point is of great importance. For if, as I believe will be the case, these mental conflicts become generally recognised as the main causative factor in many instances of delinquency of all kinds, and not merely of sex offences, it follows that suitable provision, institutional or other, will have to be made for their proper treatment. It is suggested, not—as some appear to imagine—that these cases are to remain untreated, and the patients allowed to do whatever they please, but that the present method of treating them by punishment is altogether inadequate. I have included under this heading only those cases in which it appeared to me to be quite certain that a mental conflict was at the root of the trouble. These conflicts were of very varied character. Some were due to repression of early sex experiences or of sexual imagery. There were cases in married men in which the sex desire could not be gratified in the normal way because of objection on the part of, or separation from, the wife, accompanied by disinclination for extra-marital intercourse. And there were some cases among the younger unmarried men in which normal sex indulgence was prevented by ignorance, nervousness, or fear of consequences. I am not, of course, implying that unbridled or indiscriminate sex indulgence is to be advised in these, or in any other cases. The point is that in these cases there was failure to find satisfactory substitution.

The conflict cases were much more numerous among the younger men, 71 per cent. occurring in those under 30 years of age. This agrees with Healy's findings.[6] It is uncommon in my experience, as in his, to find evidence of mental conflict among older offenders, but the start of their delinquent careers may have been produced in this way. It may also be noted that the conflict cases were slightly more numerous among the exposure offenders. Investigation of a far larger number of cases is required on this point, but we might, perhaps, expect the findings of this present series to be confirmed. Indecent assault is a much more "understandable" offence, and that satisfaction may result therefrom is much more obvious. The offence may simply be a preliminary step to actual sex connexion. But the satisfaction derived from indecent exposure is far more difficult to comprehend. The patient himself often experiences this difficulty, and cannot explain why he committed the offence. This is the case with all offences due to mental conflict. There is often a peculiar absence of satisfaction resulting from the offence itself. The patient experiences a sense of impulse towards some action, a sense of tension, and the action results in relief of that tension. There is, to that extent, satisfaction, but there may be no more than that. It is an infantile type of reaction to endeavour to dispose of an idea by means of repression, and then to try to obtain some satisfaction for the instinctive desire which it connotes. It is an instance of the infantile character of the unconscious.

The high percentage of mental conflict cases in this series is confirmed by my studies of offenders of other kinds, as well as by the researches of other workers in this field. And it becomes clear that mental conflict is one of the most frequent causative factors in the production of delinquency. It is likely that further work will demonstrate that this is absolutely the most frequent factor. The implications involved in this finding open up a vast subject, which cannot be entered into here. But our entire conception of the cause of many offences, and of their rational treatment, will have to be radically altered. It may be true that some of these cases, for various reasons, are unsuitable for any form of treatment by mental analysis. On the other hand, many are most eminently suitable for this form of treatment.

The previous history of the cases was investigated as far as was possible. And the statements made, on this head, by the patients themselves were checked as far as possible. The absence of "field workers" was a great hindrance here, and this defect will have to be remedied in any future extension of this work. Friends and relations of the offenders were seen by me whenever such an arrangement could be made. Much useful information was obtained in this and in other ways. But this information does not lend itself to statistical presentation. The previous convictions of the offenders can, however, be given with a fair approach to accuracy. Of the exposure cases 14 (28 per cent.) had been previously convicted of similar offences, and 6 (12 per cent.) had been previously convicted of offences of other kinds. For the assault cases the figures were 11 (22 per cent.) and 9 (18 per cent.) respectively. That 25 per cent. of the whole series had been previously convicted of similar indecent offences is a very striking fact.

Necessity of Examination Before Conviction.

I am well aware that the whole number of cases is not large. I have had to choose between the intensive study of a small number of cases and the superficial examination of a larger number. In my view, the former of these two courses is the only one worth adopting. To assign some factor as a "cause" for delinquent actions, after a superficial inquiry, is a course which has been adopted far too often in the past. Many cases of other kinds have, of course, been examined during the period under review. The facts and figures of the present series are given rather as indications for the lines of future most necessary research than as a basis for any sweeping conclusions. But there is one inference which we may fairly draw. In only 17 per cent. of the cases in this series was the result of mental examination negative. And even among these negative cases there was evidence that one man had been previously certified as insane, in two cases chronic alcoholism was present, and one man was ultimately found to be suffering from a cerebral tumour. These facts surely

indicate the pre-eminent necessity for the fullest investigation of these and of other offenders. Such examination should precede conviction. This is the only logical procedure. And, further, the results obtained by examination before conviction are far more satisfactory than are those obtained by examination after conviction. The patient is at his best when he feels that he presents a problem which the examiner desires to solve. When conviction has taken place a new attitude of resentment is often set up, and this may persist for some time. I have dealt with this particular aspect of the matter more fully elsewhere.[7] Until mental examination has been made, a court is quite in the dark as regards the most important feature in the case. And it is much to be desired that certain kinds of offence, including all "sex" offences, should be investigated by an examiner possessed of knowledge and experience before they are finally adjudicated upon. We have now adopted the position that no person should be physically damaged by punishment, if such damage can be prevented. It would seem that this principle should apply to possible psychical damage. Yet there is no doubt that psychical damage is often caused to these subjects of mental conflict by imprisonment without proper mental treatment. The harm done by the indiscriminate serving out of sentences of imprisonment has been recognised by the Probation Act and by other legal enactments; there seems to be at the present day a marked tendency to make every effort to avoid sending any offender to prison. Indeed, it may be that harm is now done by placing some of these mental conflict cases on probation without any condition as to proper mental treatment. The whole question requires to be put on a sounder footing. And the intensive investigation of the individual offender is the key to the whole position. That the necessity of such investigation requires to be recognised by courts is shown by the fact that, of the 100 cases reviewed in this paper, no less than 15 were sentenced to imprisonment without any preliminary mental examination. These 15 cases included two of the insane men, all the six imbeciles, and four other mental defectives, and one case of subnormal intelligence.

This paper is published with the permission of the Prison Commissioners, but it must be understood that only my personal views are expressed therein.

NOTES ON AN OUTBREAK OF EPIDEMIC ENCEPHALITIS WITH PAINFUL ABDOMINAL SPASM.

BY ARTHUR J. HALL, M.D. CAMB., F.R.C.P. LOND.,
PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD.

THE constancy with which successive outbreaks of epidemic encephalitis have occurred at or about the same time in each year has been noted in all countries since its first appearance. It is just six years [1] since a small outbreak in this district ushered in the disease to this country, and true to its time, almost to a week, there is now a similar outbreak here rather more extensive in numbers. In this brief note I wish to call attention to certain features of this outbreak, which although containing nothing that has not been previously noted in other outbreaks in other parts, presents certain characteristics which have not been previously common here.

[1] THE LANCET, 1918, i., 568.

Nearly every outbreak differs to some extent from those preceding it in the same area, by the local predominance of some symptom or type. Thus, whilst among the present series there are classical cases of the oculo-lethargic and of the choreatic type, these do not form a large percentage of the whole. Most of the cases, on the other hand, show the following group of symptoms, one or more being particularly prominent in different cases.

1. Intractable initial insomnia, going on for many nights.
2. Delirium, in which throughout the whole night the business affairs of the day are repeated with merciless persistence (occupation-delirium). At times they become violent, but this is the exception, and does not, as a rule, persist.
3. Disorders of the respiratory mechanism. Attacks of dyspnœa with polypnœa, or irregular deep breathing. These occur mostly in the night and may continue during sleep. In some they have been present also during the day. They are quite unlike anything else, and in some cases have been the initial symptom.
4. Acute painful spasm of some muscle or group of muscles of the abdominal wall, the so-called abdominal myoclonus.
5. Ocular phenomena either in the form of loss of upward conjugate movement, with inability to raise the upper lids, or more general weakness of eye movement, and consequent disturbance of vision, the details of which it is difficult to ascertain. In some cases there is even a "visual apraxia." Nystagmus is common.

As stated above, marked lethargy has not been common. Fever is usually slight. A very foul tongue and obstinate constipation are usually present. It is, however, to the symptom of abdominal myoclonus that I desire to call particular attention. Unless its true nature is realised there is danger of it being mistaken for an abdominal emergency, which it may closely simulate. I have seen two cases, one in which it was thought to be an acute pleurisy, another renal colic. At onset it is the cause of very severe pain which recurs with every violent spasm of the muscles, and these may be firing off every second or at rather longer intervals. As time goes on they seem to cause less pain and indeed to go on without disturbing the patient at all. Why this is so I do not know, as the spasms seem as violent as before. Although any muscle may be involved, in all the cases I have seen the spasm has been either in the upper part of the rectus abdominis, either one or both sides, or in the left external oblique. The spasms recur at frequent intervals. They vary in depth, and in regularity. Tracings of them show some interesting features, but their investigation is not yet complete.

In the cases in which both the upper recti are involved the spasms may be, and often are, synchronous, but in one case they tend to alternate, first one side then the other contracting. That these cases, in which there is apparently nothing else than the painful abdominal myoclonus (the algo-myoclonus of Cruchet), are identical with other forms of the disease is shown by the series of cases here, for there has been every gradation from these to cases with slight other symptoms and finally to severe and even fatal cases showing lethargy ocular and other cranial nerve palsies, &c. As a matter of fact, almost every case in which this myoclonus is present will show on careful inquiry or full examination quite definite stigmata of the disease. You will find that there has been occupational delirium for a night or two, or something queer about the breathing, or a temporary complaint as to vision, or that there actually is some unsuspected disorder of eye movement in some direction, or unequal pupils or possibly a nystagmus.

A considerable number of cases of so-called epidemic hiccough has also occurred here recently, and one of the abdominal myoclonus cases was said to have had this at the onset, but I am not quite certain of this. Most of the hiccoughs clear up in three or four days, whereas the clonus may continue for several weeks.

THE SPEECH CLINIC.

BY E. W. SCRIPTURE, M.R.C.S. ENG., M.D. MUNICH,

PROFESSOR OF EXPERIMENTAL PHONETICS IN THE UNIVERSITY OF VIENNA; MEDICAL OFFICER, SPEECH CLINIC, WEST END HOSPITAL FOR NERVOUS DISEASES.

THE death of Prof. Hermann Gutzmann, of Berlin, affords an occasion to consider the department of medicine which he did so much to create. That the abnormalities of speech were of very great importance, not only for purposes of diagnosis but also as instruments for pathological research, had long been recognised by such men as Brücke, Kussmaul, and others, but down to about 20 years ago no one had devoted himself to speech pathology as his life work. Prof. Gutzmann was one of the first to do this. In Berlin he developed a well-equipped speech clinic and laboratory for studying speech abnormalities. For many years he edited the *Monatschrift für die gesammte Sprachheilkunde* which was later merged in *Vox*. He instructed large numbers of medical students to understand speech and to treat the various forms of speech defect. One of his pupils has established a similar laboratory in Vienna. Many medical men have studied the subject with a view to adding it to their regular work.

Outside Germany little has been done. Shortly before Gutzmann took up work at Berlin, I started a speech clinic at the Vanderbilt Clinic in New York city. For the last seven or eight years I have conducted a speech clinic at the West End Hospital for Nervous Diseases in London. Otherwise, as far as I can learn, nothing of the kind has been done in England.

Lack of Knowledge of Speech Phenomena in England.

The most striking fact of the situation in England is the complete ignorance of speech phenomena, not only among practitioners but also among neurologists and laryngologists. For more than fifteen years I have been in constant association with neurologists and have never met one who could diagnose the dysarthrias correctly. Any muddled kind of speech is said to be a dysarthria. The most frequent dysarthria of all, that of the larynx, is never recognised. The most prominent feature of all dysarthrias—the effort to overcome the defective action of the speech mechanism—has remained absolutely unknown. I have often pointed out that the most prominent feature of speech in a case of disseminated sclerosis is not the ataxia, but an effort to overcome the ataxia—that is, what may be called "anataxia." I can remember the surprise and pleasure of a distinguished neurologist when I compared an inscription of a case of Landouzy-Dejerine with normal ones, and showed how the former was pathological just because it was too perfect. In a case of Friedreich's ataxia this over-perfection in enunciation was likewise found; the disease made itself evident only in the longer time required. Of the speech signs in more central troubles the ignorance is complete. Every medical student knows that to stumble over "third riding artillery brigade" is a sign of general paralysis, but not even the best neurologist has the faintest notion of what the patient really does when he stumbles or why he does it. In the earlier cases the neurologist regularly misses the speech defect because he does not know what to look for. Other forms of speech defect remain quite unknown. The epileptic voice is just as characteristic and clear a sign as any dysarthria, and the ear can be trained to detect it. Year after year I have sat in nerve clinics and diagnosed the cases as epilepsy or not epilepsy by the manner in which the patient begins to speak. Although a trained ear never makes a mistake, the neurologists are quite ignorant of the existence of this sign.

The laryngologist contents himself with what he can see. He considers that when he has treated any organic trouble or has recommended an elocutionist his duty is over. He does not bother himself about the inner nature of the defect or its cure. Owing to their lack of information medical men in general never make any attempt to give an accurate speech diagnosis. When confronted with one of the special speech defects, all they can do is to state that the case is hopeless, or will cure itself, or had better be taken to an elocutionist.

Function and Equipment of the Clinic.

The solution of the difficulty lies in the establishment of speech clinics for diagnosis, research, and instruction. Such a clinic can justify its existence in the first place by what it can do in the way of diagnosis. It can—by the method of making speech inscriptions, and studying them under the microscope—furnish accurate diagnoses of general paralysis and disseminated sclerosis at a stage so early that no speech defect can be heard. Let it be remembered that general paralysis has been cured if treated by malaria at an early date. Let the possibility be remembered of mistakes between early disseminated sclerosis and hysteria, so that we may be careful not to send a case of the former to a psycho-analyst. Let it also be remembered that early cases of disseminated sclerosis can be cured by the Wagner-Jauregg method. The inscriptions of adiadokokinesis and other manifestations of dysmetria are so easy to make, and so striking, that they are useful in telling when the cerebellum is diseased or involved in a tumour.

Equally important is the service of a speech clinic for the purposes of research. Inscriptions of epileptics always show a peculiarity that has never been found in any other disease. They furnish a proof of the view that idiopathic epilepsy is not a disease of the cortex, but a special condition of the patient's character.

A third claim for the speech clinic is its usefulness for treatment. Over 600 cases of laryngectomy have been taught to use ructus speech at the Phonetic Laboratory in Vienna; many of them have been restored completely to work even when telephoning is involved—that is, they were taught to speak audibly by air from the stomach, although they had no larynx and breathed through a cannula. In the clinics at Berlin and Vienna the treatment for the various forms of aphonia has reached a high degree of efficiency. I have found that, in combination with other methods, the training of epileptics to eliminate their peculiar voice is followed by improvement in the general condition. The treatment of stuttering on the basis of clinical researches would put an end to the present methods of the elocutionists.

A further claim is that of usefulness for instruction. Speech is the most complicated and delicate manner in which mind and nerves express themselves. It contains more kinds of diagnostic information than many another manifestation, and its pathology, if properly learned, is as useful to the practitioner as a urinary analysis.

One obstacle to the establishment of speech clinics has been the difficulty in obtaining the apparatus required. To various inquirers in the past I have been obliged to reply that the only recording drums of sufficient accuracy were an expensive one made in Leipzig and a cheaper one that could be made to order in America. The speech recorders could be obtained only in Paris. The highly important laryngostroboscope could not be obtained anywhere. This obstacle has now been completely overcome by what might be called the fortune of war. Under the new government the Ministry of War of Austria teaches every soldier a trade. One department of the instruction is that of making fine apparatus. All the apparatus for speech work is now duplicated with a fineness and precision equal to and often better than that obtainable by the best German and French mechanicians. The crux of the matter lies in the fact that it is forbidden to charge for the labour or to make a profit. The only charge is for the cost of the raw metal used. A complete speech laboratory can be equipped for a sum so modest that even the poorest hospital need not think twice about it.

Clinical and Laboratory Notes.

UNCOMMON CONDITIONS ASSOCIATED WITH LIVER LESIONS.

BY F. J. O'DONNELL, M.R.C.P. IREL.,
RESIDENT MEDICAL OFFICER, BAGTHORPE INFIRMARY, NOTTINGHAM.

THE following cases seem worth recording from both the clinical and the pathological standpoint, as the clinical course in each case was unusual, and the post-mortem findings, especially in the liver, uncommon.

CASE 1.—A girl, aged 8, admitted to the Bagthorpe Infirmary on Nov. 9th, 1923, suffering from extreme hoarseness and sore-throat. Temperature 99° F. She was put on salicylates, and the temperature dropped. On the 16th the temperature went up to 102°. Examination only revealed a faint apical systolic bruit, and a rather sharp pulmonic sound. Next day the child was intensely ill—ashen, drawn face, sordes on lips, and tongue like leather—not at all unlike the extreme toxic appearance of a patient dying of peritonitis. The temperature ran an intermittent course, reaching 103° on a few occasions. Examination revealed nothing further until the 20th, when signs of consolidation appeared in the left lung. The child died on the 25th.

Post-Mortem Examination.—Extensive pleural adhesions at left base, which was pneumonic. Aortic and mitral valves intensely inflamed. Neither valve was ulcerated, but when opened out the cusps formed a bright crimson line across the ventricle. Tricuspid valve also inflamed in parts, but not so extensively. Abdomen distended and full of fluid of ordinary ascitic type. Liver was greatly enlarged and typically "hobnailed." Spleen enlarged, and pancreas felt abnormally hard. Sections of liver showed characteristic unilobular cirrhosis, and sections of pancreas showed extensive fibrosis.

CASE 2.—Male, aged 22, admitted on Nov. 23rd, 1923, with a diagnosis of influenza, having been ill a fortnight. He gave a history of having had several attacks of "boils," but on admission showed no evidence of a current attack. His temperature on admission was 100·4° F., and except for severe pyorrhœa examination revealed only some impairment of resonance and breath sounds on right side of thorax posteriorly. Patient was unusually drowsy, and as his chart suggested in the course of a few days a septicæmia, a blood culture was performed. This gave a pure growth of *Staphylococcus aureus*. On the 28th exploration of the right base gave a slightly hazy fluid mixed with much blood. On this day, also, a septic rash appeared on the arms, and the patient was incontinent at times. On Dec. 3rd exploration at a lower level than previously discovered abundant pus. Resection of a rib had an unexpected sequel—the pleural cavity contained no pus, and an abscess of the lung was regarded as the site of the pus. Next morning the patient had a right parotitis and died that day.

Post-Mortem Examination.—Bases of both lungs pneumonic, with marked purulent pleurisy. Heart and aorta small, but no valvular lesion in heart. A large abscess *in* the right lobe of the liver in its upper aspect almost on the point of rupture. The abscess appeared localised and apart from it the liver did not present a pyæmic appearance. The spleen was enlarged and the kidneys congested.

Remarks.

Case 1 is chiefly of pathological interest in view of the intense widespread inflammation of the valves of the heart and the extreme cirrhosis of the liver in a child of 8. How far this cirrhosis contributed to the extremely toxic state of the child invites speculation.

In Case 2 arises the question of the origin of the septicæmia. The patient had never been abroad, and had no history of dysentery. The extreme pyorrhœa, or the lighting-up of a dormant focus left after one of the attacks of "boils," both seem possibilities. (A similar fatal septicæmia occurred recently in a boy aged 18 without any obvious focus, but six months previously the boy had a severe septic finger which apparently healed completely.) As regards locating the pus, if the abscess had been in the lung, the latter would probably have been adherent to the parietal pleura, while the empty thorax, the height of the diaphragm, and its tenseness, should have suggested a subdiaphragmatic source.

A CASE OF INTRAPERITONEAL OVARIAN PREGNANCY WITH A FULL-TERM CHILD.

BY S. SUVANSA, M.R.C.S. ENG.

(From the King Chulalongkorn Memorial Hospital, Bangkok, Siam.)

THIS case is recorded as intraperitoneal pregnancy with a full-term and living child is unusual.

A married woman, aged 37, was admitted into the maternity ward of the hospital, under the care of Phya Damrong-baedyakun, on August 9th, 1923, complaining of abdominal pain and bleeding from the vagina.

History of Present Condition.—In December, 1922, patient missed her period, but in January the flow appeared again and at the expected time, lasting seven days. It was, however, offensive. Since then there had been complete amenorrhœa. At about this time she suffered somewhat from morning vomiting and frequency of micturition. No change in the breasts was noticed by patient until a few months ago, when they seemed to be distended and a little yellowish secretion could be squeezed out. The child was first felt to move about the fifth or sixth month. Two days before admission patient bled from the vagina. A doctor was called in, who diagnosed the case as antepartum hæmorrhage, and sent her to hospital.

Past History.—Patient had been in good health. Her periods had been regular, being present at intervals of 28–30 days, lasting four to seven days. There had never been any leucorrhœa. Patient had suffered from indigestion for the last four to five months.

Family History.—She had had five pregnancies, of which there were three children and two miscarriages (the second and fifth, each of about seven to eight months). The latter miscarriage happened in 1916. In 1919 patient, who had lived with her husband since marriage, obtained a divorce and married another man. The present pregnancy was the first after the second marriage. Her second husband is 24 years of age.

Condition on Admission.—Patient, who appeared quite calm, was a thin and somewhat pale-looking woman. The temperature was 98° F. and the pulse-rate 110. The pupils reacted well to light and accommodation. The conjunctivæ were slightly pale. The breath was foul, though the teeth were fairly good. There were no enlarged glands felt in the neck. Nothing abnormal was found in the lungs or heart. An oval lump was seen in the abdomen, which reached from the symphysis pubis to about 2 inches above the level of the umbilicus. Its long axis was from the left below to the right above and about 45° to the vertical. Knobs were seen on the lump. The abdominal wall was thin, and the lump was recognised as a fœtus lying in the left occipito-anterior position. A limb could be picked up between the fingers when the fœtus made a convulsive movement. The fœtal heart-sound was heard near the umbilicus. The vaginal orifice was covered with varicose veins. The speculum was carefully inserted, but one of these bled. It was immediately ligatured. The cervix was found enlarged, œdematous, rather soft, and mauve-blue in colour. When it was moved there was no transmission to the lump in the abdomen. On withdrawing the examining finger a somewhat profuse bleeding from within the cervix occurred, the blood being bright red.

Diagnosis.—As the abdominal wall was thin and the fœtal parts could be so easily palpated, and no uterine contraction was obtained, a diagnosis of extra-uterine pregnancy was made. The bleeding from within the cervix, however, could not be explained; but in a former case of extra-uterine pregnancy which was admitted into hospital not more than ten days previously—a remarkable coincidence—and had a fatal termination, there was also bleeding from within the cervix.

Treatment.—As the bleeding stopped of itself, and as the patient appeared very weak, operation was postponed and a careful watch was kept over her. On the 17th the child was kicking continually, causing a faint feeling with severe abdominal pain; and blood was observed to flow from the cervix more profusely than before. The uterus and the vagina were thereupon packed with strips of gauze, and an immediate operation was decided upon.

Operation.—The patient was placed in the dorsal position. The skin was cleaned with absolute alcohol and swabbed with iodine. An incision was made in the median line extending from the umbilicus to the symphysis pubis. Skin and the fasciæ were divided until the peritoneum was seen. This was picked up and carefully divided, when the breech of the fœtus became exposed. The right hand was introduced into the abdominal cavity, and the child was seized by the legs and delivered. It was quite blue. The

mouth was swabbed with gauze and the umbilical cord ligatured and divided.

On examination the placenta was felt adherent to the under surface of the liver and the right side of the abdominal wall. It had a downward process which seemed to envelop the right ovary and the cæcum. The uterus was about the size of a three months pregnancy, and was somewhat flabby. The uterine tubes and the left ovary looked normal. The infundibulum of the right tube was implicated in the placental process. The placenta was left in situ for fear of uncontrollable bleeding if removed. The abdominal wall was closed in separate layers. The patient was under chloroform in five minutes, and the child was delivered five minutes later. The whole operation took 25 minutes. When the abdominal cavity was opened, a little clear fluid was observed. No membranes were found, but when the child was delivered a portion of the membranes was seen capping its head tightly.

The Child.—The child remained blue and refused to cry, breathing weakly for fully five minutes, during which it was placed in a warm bath and slapped, and artificial respiration was applied. Though it could breathe better, it was still somewhat blue for three days after. No congenital heart disease was detected. The child was a full-term and weighed 2260 g., or 5 lb. (The average weight for a Siamese new-born is 3000 g., or 6½ lb.)

Later Notes.—At the end of 24 hours the vaginal plugging was removed; the bleeding had stopped. Much anxiety for the child was felt on account of the cyanosis. Small quantities of warm water were given during the first day. On the second day it was put to the breasts of a woman who had just given birth to a child in the same ward, and who had enough milk for two. The mother had been feeling very weak since the operation. Her breasts contained little milk, which was withdrawn with a breast-pump, as it caused an uneasy feeling in the organs. Some anxiety was still felt as to what might happen to the placenta. On the 24th the wound had healed. The temperature and pulse had been about normal. Patient felt somewhat weak and appeared listless. On the 31st, till which day the patient had been feeling weaker and weaker, the temperature went up to 103° and the pulse-rate to 90. On Sept. 9th the temperature, which had come down somewhat, went up again to 104°. The patient became very weak, and died at 1.30 A.M.

The child (a girl) has been and is progressing satisfactorily. Its weight has been increasing as follows:—Fed on human milk: August 24th, 2260 g.; Sept. 1st, 2440 g.; 7th, 2540 g. Fed on bovine milk: Oct. 1st, 3250 g.; 8th, 3410 g.; 15th, 3470 g.; 22nd, 3750 g.

Post-mortem Examination.—The heart, liver, spleen, and kidneys were soft and pale-looking. In fact there was general anæmia. To the under surface of the abdominal wound were adherent the great omentum and anterior portion of the placenta. The placenta itself was roundish in shape, lobulated, and contained in a capsule, looking very much like a multilocular ovarian cyst. It was attached to the end of the right uterine tube by a stout stalk, and the right ovary could not be found. The left tube and ovary were natural in appearance. The uterus was about the size of the fist. The placenta was anchored by adhesions to the omentum and bowels which were easily stripped off from the capsule, when the mass became free save at its lower attachment to the tube. The placenta did not look infected, but the general peritoneum was dull-looking, congested in a few places, and appeared thickened. Section of the placenta showed presence of lymphocytes in the region beneath the capsule.

Death was presumed due to lowering of body resistance following chronic peritonitis and general anæmia.

THE LATE DR. W. B. BETENSON.—The death occurred at Newhaven on March 8th, after a long illness, of Dr. William Betenson Betenson. A native of Suffolk, he studied medicine at St. Bartholomew's Hospital, and in 1888 took the L.S.A. diploma and became L.R.C.P. Lond. and M.R.C.S. Eng. For some time he was house surgeon at All Hallows County Hospital, Ditchingham, and in 1901 started practice at Newhaven. He became attached to the local R.N.V.R. in 1904, and during the late war he had a distinguished record. He went to the Dardanelles as surgeon-commander on H.M.S. *Bacchante* (1914–16) and later served on H.M.S. *Powerful* at Devonport. Afterwards he served with the R.N.V.R. at Newhaven. Dr. Betenson was popular in the service and also as a private practitioner, and despite an extensive practice he found time to identify himself actively with public affairs. Before the war he was a member of the Newhaven Urban Council and for a year held the position of chairman with a seat on the magisterial bench. For many years he was medical superintendent at the Union Infirmary, Newhaven.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ELECTRO-THERAPEUTICS.

CLINICAL RESULTS OF DEEP X RAY THERAPY.

A MEETING of this section was held on March 21st, when a discussion was held on the Clinical Results of Deep X Ray Therapy. Dr. WALTER J. TURRELL, the President of the section, was in the chair.

Dr. WILLIAM MITCHELL (Bradford), in opening the debate, explained that his remarks would be based on 20 years of experience at Bradford in radiotherapy, and that his technique was that recently described by Vince in his book. As a result of much unwise comment in the press, a much greater demand for X ray treatment had been made than was justifiable, many false hopes were raised, and those who had been feeling their way on the subject had found their hands forced, for it came to be regarded as almost a crime to refuse to treat a case in this way, however hopeless it might be judged. Of 133 malignant growths treated 30 were carcinoma of the breast, 28 epithelioma of jaws, tongue, and larynx, 1 of forehead, 8 cancer of the pelvic colon and rectum, 7 of cervical glands, 2 of superior maxilla, 4 sarcomata, 2 carcinoma of the body of the uterus, 20 of the cervix uteri, 2 of the pancreas, 2 sarcoma of skull, 1 chondro-sarcoma of pelvis, 1 epithelioma of ear, 2 carcinoma of kidney. Stomach, bladder, and rectal cases, 1 osteo-sarcoma of clavicle, and 1 myeloid sarcoma of the head of the femur, sarcoma of buttock and lympho-sarcoma of neck. Hodgkin's disease, uterine fibroids, carcinoma of thyroid, splenic leukæmia, and some minor conditions were also treated. Forty-eight of the 133 cases were hopeless before treatment was commenced, and 46 of the cases were post-operative recurrences. At the end of a year 41 had ceased attending before completing their course, many because their doctor advised them that the treatment was probably doing them more harm than good, some because they felt the treatment was upsetting them. Of two cases of cancer of the cervix uteri, both of which he at one time thought were cured, one had a severe recurrence and refused to have further treatment. In two cases of carcinoma of the pelvic colon who had had colotomy performed, the result of the treatment seemed good, and one was still living, though with a fæcal fistula. One case of carcinoma of the bladder, in which that viscus had been opened and cauterised, he had treated six times with a 20 per cent. dose, at the end of which course the man was in good condition, nothing could be felt per rectum, and urine was passed easily. After each treatment the urine remained clear for three months, but then blood reappeared in it. The four breast cases appeared to do very well. A case of lympho-sarcoma of the neck at one time seemed cured, but there was a recurrence, and death took place from pulmonary metastasis. A myeloid sarcoma of the humerus, in a girl aged 6, was cured by the treatment; he exhibited skiagrams showing the regeneration of bone which had taken place. Tuberculous dactylitis did well, as indeed it did in former days, with the old treatment. It was, he thought, impossible to promise cure of malignant disease by X ray therapy, chiefly because metastasis was an unknown quantity before treatment was commenced. If a case were treated while in a hectic condition, it was probably made worse than before. The most favourable cases were those with a good blood count and high hæmoglobin index. There was a difficulty in regard to beds in hospitals for the treatment of these cases, hence in too many cases these patients, after each séance, had to return to their squalid and insanitary homes, a fact which seriously militated against good results. Practically all cases, excepting the hectic ones, received temporary benefit from the treatment, and expressed themselves as much fitter in general health.

The Dual Effect on Patient and Growth.

Mr. SAMPSON HANDLEY said the time had passed when surgery alone could claim to deal with malignant disease; in nearly all cases the help of the radiologist was necessary. Yet he was not clear that what was known as deep X ray therapy was the sort of help the surgeon would ask. The effects of deep X rays on patients with malignant disease should be placed under two headings: (1) the effects on the patient; (2) the effect on the growth. The former still stood in need of investigations by the biochemist, and those made at Middlesex Hospital by Dr. E. C. Dodds and Dr. J. H. D. Webster[1] deserved careful consideration. The former had thoroughly investigated a few cases, rather than more cursorily examining a large number, an intensive method of study which the speaker commended. These observers had found that while irradiation of the head, neck, and thorax had little effect on the urine, irradiation of the abdomen profoundly modified the urine, producing an immediate large drop in its amount and a variation in its essential constituents. They attributed this to a temporary inhibition of the functions of the principal abdominal glands, such as liver, pancreas, and kidneys. When the abdomen was irradiated there was a marked fall in the blood-urea content. Patients subjected to heavy X ray doses, especially applied abdominally, suffered from profound asthenia and loss of vitality—i.e., to a degree greater than could be accounted for by the disease for which they were treated; in this X rays afforded a striking contrast to the results of treatment by radium, which appeared to have a stimulating action, giving the patient a sense of increased well-being. Even sufferers from inoperable malignant disease had told him, when being treated by radium, that they had never felt so well in their lives. The effects of deep X ray therapy in amounts necessary for the surface treatment of deep-seated tumours were so marked that in such amounts the use of the rays was undesirable and deleterious. As to the effects of irradiation on the tumour itself, in certain cases there was undoubted benefit, while in others, actual stimulation of the growth took place. Mr. Handley proceeded to describe some cases. In the case of three patients who were subjected to deep X ray therapy, within a short time of the commencement of the treatment, new superficial metastases developed within the area treated. One was a breast carcinoma with recurrent nodules. Deep therapy had been carried out for the nodules, but fresh ones appeared there. Another was a carcinoma of the neck, with a recurrent mass just below the jaw secondary to carcinoma of the larynx, and shortly after deep therapy had been applied to the neck, the scar was a mass of secondary nodules along its length. In the third case the speaker excised part of the stomach for gastric carcinoma. Deep therapy was applied prophylactically, because he felt his operation must have been an incomplete one. Within two months of the treatment having been commenced, masses could be felt deep down in the abdomen. In one case of retro-peritoneal carcinoma, the primary growth probably being in the pancreas, for a mass could be felt there, enlarged glands existed in the right iliac fossa. That was in September, 1922. He thought the patient's life would be about three months. Dr. Douglas Webster applied deep therapy, after which the glands in the right iliac fossa disappeared, the patient seemed much better, and began to get about again. But the mass above began to grow again, and death took place two months ago. In that case he believed the deep therapy prolonged life about a year. For a man with carcinoma of the prostate, Mr. Handley buried radium into the lateral aspect of the prostate through punctures in the perineum. Improvement followed this, but he still had a mass in the right vesico-sacral fold, palpable per rectum, and he developed some glands in the right iliac fossa. After this one radium application, Dr. Webster treated the patient by deep X ray therapy, having begun it in February, 1922. If the case had been left the patient would probably have been dead by now, but he was still going on, all the glands in the left iliac fossa had disappeared, and the former œdema of the left leg had now gone. An opinion on the efficacy of the treatment was only possible after a long period of observation of cases. The technique was still fluid. His general view was that a medium must be observed between an X ray dosage which was inadequate to act on the growth and that which was harmful to the patient, and he did not think that balance had yet been effectively struck. The use of buried radium, in suitable cases where the area to be dealt with was small, possessed great advantages over deep X ray therapy, in that, with the radium, application of a maximum amount of irradiation of the growth could co-exist with a minimal irradiation of the tissues generally. In deep X ray therapy, however, irradiation of the tissues generally was hard to avoid, and was usually deleterious in its effects.

[1] THE LANCET, March 15th, 1924, p. 533.

Favourable and Unfavourable Conditions.

Dr. G. COOPER (Leeds) spoke from an experience of 400 cases of all varieties of malignancy. In most of the cases in which X ray therapy was applied there was a marked improvement in general health and an increase in weight shortly after the commencement of the treatment; it seemed as if the growth had been temporarily checked in the intensity of its malignancy. Pari passu with this there seemed to be a staying of toxic action. A decline in general health seemed to be associated with a return of activity of the growth. There was in many cases a cessation of discharge and relief of pain following the treatment, and, particularly when hard rays were used, a formation of fibrous tissue, the latter being probably an important factor in limiting the spread of the disease. Healing of rodent ulcer coincided with the formation of a dense layer of scar tissue, which cut off the normal from the malignant cells. Among the factors influencing the degree of response to the treatment were the amount of metastasis, the situation of the growth, the condition of the patient, especially the blood condition, the nature of the neoplasm, and the amount of irradiation administered. His best results had been obtained in genito-urinary conditions and pelvic conditions generally, but cancer of the cervix had shown a tendency to relapse, after the first improvement which practically always took place. By means of this therapy many cases adjudged inoperable had been rendered operable. There were also encouraging results in cancer of the rectum; pain was controlled, and the size of the growth reduced. Except in one case (in which the radiation was given at the time of operation) he had found the treatment in cancer of the stomach very unsatisfactory; nor had there been a favourable response in cancer of the tongue. A much more favourable report could be made concerning the treatment of primary glandular enlargements. In cancer of the parotid and thyroid glands, he had had good results at first, but nearly every such case subsequently developed metastases. The urgent dyspnœa of malignant disease of the mediastinum was often relieved by the treatment, but relapse occurred in three or four months. In spleno-medullary leucocythæmia an enormous reduction in the size of the spleen was effected in two or three weeks. Since the introduction of deep therapy more advanced and definitely hopeless cases were brought for treatment; it offered the only treatment likely to bring relief, and it could be said that more had been done for malignant disease by it than had hitherto been achieved outside the domain of surgery.

The Response of the Body Tissues and Fluids to Radiation.

Dr. ROBERT KNOX reminded the meeting that deep X ray therapy was not by any means a new departure, and it did not originate at Erlangen; in this country it had been steadily developed along sound lines. It was assumed that a particular lesion of the skin stood

a certain dosage, and that if there were a deeper-seated lesion it would respond to a similar dose. Deep therapy was based upon that: it was a logical extension of surface therapy, and was a question of wave-length. The points he wished to make were largely based upon Mr. Sampson Handley's work on the natural process of cure in cancer embodied in his book on cancer of the breast. It was necessary to supplement nature's efforts at cure: instead of depressing the tissues, efforts should be made to enable them to overcome the disease. In many cases that was what the radiologist did. In treating blood conditions in this way it was found that the blood cells responded in various ways to irradiation, and one of the lines of inquiry should be concerning the alterations in blood, blood serum, and the various biochemical processes. The work of Dodds and Webster was very fine in this respect, and if pursued would take the profession a long way in a rational therapy, and probably standardise the technique. The response of enlarged lymphatic glands to irradiation he had found to be remarkably rapid; not so rapid in lymphadenoma, less rapid still in lympho-sarcoma (and a greater tendency to recurrence). In sarcoma the reaction was not so certain, and in carcinoma there was an uncertain reaction. Dr. Knox then referred in detail to a number of cases and projected slides of them on to the screen. One of the most remarkable was that of a man who six years ago had a testicle removed for a carcinomatous condition. He had fairly frequent doses of X rays for two years. He then came with a large mass in his abdomen, which was regarded as malignant. A fairly heavy dosage was applied, and it disappeared in a remarkable manner. Early last year he came with a mass of glands in the supra-clavicular region, and had pleural effusion at the left base and a very large mediastinal tumour. Penetrating rays in considerable dosage were administered, and the left pleural effusion cleared up. The tumour was much reduced in size, but there was later effusion at the right base. In the course of time the right-sided effusion cleared up, and at present he was carrying on his duties (those of a clergyman). Dr. Knox expressed himself as a supporter of the idea that rays of lesser potency than those directed at the original growth had a stimulant action on secondaries which such rays reached, and he quoted a case supporting that view.

The Case for the Full Single Dose.

Dr. REGINALD MORTON gave some general impressions which he had formed as a result of his clinical experience. The great advantage of this modern development of X ray treatment was that it enabled one to treat centrally situated lesions with greater efficiency than superficial ones. As to the relative advantages of single and of multiple sittings, there was much to be said on both sides. The idea of the single full dose was to avoid stimulating a growth to increased activity; now and again there were cases whose increased activity could not be accounted for on any other supposition. These, however, were but a very small percentage of the whole. There was a smaller margin of error in dosage in the administration of a single dose. Even in deplorable cases giving but little hope, if X ray treatment were clamoured for it should be given. He did not think the percentage of successes from X ray treatment by modern methods was greater then formerly. In this country it was still the custom to send to the radiologist only the practically incurable cases. Hard tubes and heavy filtrations formed a homogenous means of using the rays, but they did not appear to have any more specific action on living cells. A series of cases of rodent ulcer which he had treated by the Erlangen method gave no better results than a similar series dealt with by the older technique. Some of his best results had been in pelvic conditions. Cases involving the air-passages and the neck generally were unfavourable; cartilage did not respond well to the rays. Some cases of cancer of the rectum responded very well, and prostatic involvement yielded successful results in a high percentage, especially simple enlargement of that gland as distinct from malignant conditions. In none of his cases had irradiation brought about any serious fall in essential blood cells, and he thought too much stress was usually laid on this danger. In this connexion, length of exposure was an important factor.

Dr. CURTIS WEBB spoke of the favourable results he had secured by the Erlangen method during 18 months, and related a number of cases. He favoured at present the single massive dose, in contrast to the divided dosage as mostly practised in France, chiefly because by the latter one could not be certain that the full intensity of irradiation reached the deeply situated disease.

The Combination of X Rays and Radium.

Dr. N. S. FINZI spoke of the good results achieved by deep X ray therapy a number of years ago, and instanced a case of his own, that of a boy with retro-peritoneal lympho-sarcoma, whom he treated in 1911 with hard rays filtered through 2 mm. aluminium. He was cured and was seen in good health last year. He was decidedly of the opinion that modern methods were superior to the old, and that they gave better results. The feeling was too prevalent that either X rays or radium must be used; often the best results were secured by a combination of the two. The primary growth was often best treated by radium, while the region permeated by the malignant cells could be irradiated most effectually by X rays. Also splitting the radium into two foci was valuable. Radium therapy was advancing in parallel with X rays. He agreed that the changes produced in the blood by radio-therapy had been exaggerated. Septic cases did not do so well as others, by either method. When breast cases were complicated by mediastinal involvement he regarded the outlook as bad. Giving the patient chloratone before the irradiation helped to ward off sickness.

Dr. LOUISA MARTINDALE related her experiences based upon 160 cases. She had seen very little sickness, a fact she ascribed largely to her preparation of the patient—i.e., as for an abdominal operation. Of 50 female castration cases, sickness occurred in only 2. Severe menorrhagia yielded well to X rays.

Dr. J. H. D. WEBSTER advocated a close study by radiologists of pathological processes. The best prospect from X ray and radium treatment was produced by causing a powerful caustic effect on the malignant cells, and this was effectively brought about by multiple small radium tubes. In some classes of cases the right course was to try and restrain the growth by building up the patient's health and powers of resistance. He agreed that small doses of the rays resulted in a stimulation of the new growth. There was always the danger that the area harbouring the minute seeds of the disease was not coming under the influence of the treatment. More investigation should follow the important discovery that irradiation caused the disappearance of certain types of rare blood cells.

The PRESIDENT thought a third treatment which wat worthy of consideration was diathermy. He did nos support the treatment by deep X rays of fibroids at the menopause, reminding members of the importance of the endocrine functions of the sexual organs, which were not yet fully understood. Small repeated doses seemed the best course, as being calculated to injure as little as possible the endocrine activities.

IRISH MEDICAL SCHOOLS AND GRADUATES ASSOCIATION.—The annual meeting and St. Patrick's Day Dinner of the Association was held at the Hotel Cecil, London, on March 17th. Dr. W. J. Corbett, the President, was in the chair, and the speakers included Lord Shaw and Senator Marconi. About 120 members and guests were present, among whom were Sir William Taylor, Dr. William Douglas, and Dr. Michael Bulger, past presidents of the Association.

MEDICO-LEGAL SOCIETY.

SUDDEN DEATH BY INHIBITION.

A MEETING of this Society was held at 11, Chandos-street on March 18th. In the absence of the President, Mr. W. WILLIAMS was in the chair.

Dr. PERCY B. SPURGIN introduced a discussion on Cases of Sudden Death by Inhibition, and their Medico-Legal Bearings, by telling the story of a tragedy which occurred on Oct. 11th, 1923. On that day, a day of intermingled sunshine and showers, James Murphy, a healthy and powerfully built young man of 21, took his dog out for exercise in Regent's Park. A shower drove him to take shelter beneath some trees under which Alfred Muchmore and a friend were kicking a football. Murphy's dog annoyed Muchmore and his friend by chasing the football and caused the friend to shout gruffly to Murphy to call off his dog. A few angry words ensued and then Murphy came over to the two friends and knocked down Muchmore, a much smaller man than himself, by a blow on the jaw which cut his lower lip. Muchmore and Murphy then fought until some spectators warned them of the approach of the park keepers, upon which they separated, but only to meet once more a few minutes later in another and more deserted part of the park and resume the fight. On this occasion Muchmore "knocked out" Murphy and left him lying on the ground, as he imagined and remarked to his friend, in a condition of being "winded." When he read later in the evening papers that Murphy had been found dead in Regent's Park he immediately reported at a police station and gave himself up. Dr. Spurgin was called upon by the coroner to perform a post-mortem examination three days later. Externally there were bruises on the forehead, on the left supraclavicular region, and on the thorax. Internally no abnormality was discovered other than in the heart. Both ventricles and the left auricle were so firmly contracted as to be quite empty of blood and the heart muscle itself was pale. He was driven to conclude that death was due to cardiac inhibition from stimulation of the vagus by a blow on the left side of the neck. The coroner accepted this view. Dr. Spurgin added that at the subsequent trial of Muchmore at the Old Bailey on a charge of manslaughter he was found guilty and sentenced to four days' imprisonment, which was equivalent to his immediate release.

Two other cases of death from a similar cause could be added. One, reported in the *Practitioner* of January, 1924, was that of a man of 52 who died of syncope while his wife was buttoning on his collar and thus causing pressure on the neck. In this case similar conditions were found in the heart at the post-mortem examination. Another case of death probably from the same cause was that of the English boxer Evans, who died during a contest in Holland.

Sir BERNARD SPILSBURY recounted some cases in which the cause of death was slightly different from that given by Dr. Spurgin. The first case was that of a female child, 3 years of age, who while taking a meal gave a slight cough and then fell back in her chair and gave no further sign of life. A doctor who arrived in about 10 minutes pronounced the child to be dead. This doctor was called upon by the coroner to perform a post-mortem examination, and after doing so with some reluctance, reported that he could find no cause of death. Sir Bernard Spilsbury was then called upon to make a second examination. The only striking abnormalities were the unusual lividity of the post-mortem staining, the dilatation of the heart cavities, and the large size of the brain and thinness of the skull as if from stretching. The heart muscle was pale in colour, but on microscopic examination proved to be healthy. The air-passages had been opened at the previous examination when they were found to be free of all foreign matter. His view was that death was due to a crumb having entered the larynx and caused a "reversed reflex action" which stopped all the vital functions and more especially that of respiration. The crumb had been expelled by the cough so that it was not found in the larynx after death. Many areas of the body were known stimulation of which might cause sudden death; these included the back of the nasal passages, the larynx, the upper abdomen (two cases of sudden death from a blow on the upper abdomen were reported by Sir Astley Cooper), the lower abdomen, and the genital organs. An illustrative case was that of a man of 45, who returned to his home drunk. Knowing him to be very violent in his cups all the other inhabitants of the house fled on his approach. On their return an hour later he was found dead lying head downwards on the stairs. The speaker had performed the post-mortem examination, and though he found disease in various organs was unable to account for death until he found a large bruise in the body and head of the pancreas which suggested a blow on the upper abdomen. It was then found that one of the treads of the stairs was broken, and it was surmised that the breaking of this tread had caused the man to fall heavily upon a pillar of the banisters and thus receive a blow upon the upper abdomen which caused sudden death by inhibition. In another case a boy received a blow on the pit of the stomach while fighting and fell back apparently dead; a doctor who was called found that life was extinct when he arrived. Here again the skull was thin and the brain, and more especially the cerebellum, unusually large; it seemed as if the large brain had stretched the skull. Although some thickening of the mitral valve was found the cause of death was only traced when a large bruise was found in the diaphragm in the region of the pit of the stomach. Death was, in his opinion, due to "inhibition."

All resting muscle was normally in a state of tone, but when one set of muscles contracted in obedience to a nervous impulse the opposing muscles fell into a state of active relaxation or inhibition. In the reflex produced by the entrance of a crumb into the glottis, stimulation of the vagus first stopped breathing, then followed a large inspiration, and finally an expiration through the closed glottis, in other words, a cough. In the case of the child in whom the entrance of the crumb into the larynx caused death, he believed that death was due to arrest of the respiratory function from the spread of the inhibitory effect over a wide area of the central nervous system. Death in these cases was at first only apparent, and life could be restored by performing artificial respiration until the inhibitory effect had passed off. Dr. Spurgin's case might be similarly explained; a blow on the neck caused spasm of the glottis, thus bringing the vocal cords in contact and producing the same reflex result as a foreign particle and causing the same inhibitory effect. Blows on the upper abdomen excited a similar reflex through the fibres of the vagus in the stomach; it was noticeable that in all cases where death ensued the stomach was distended with a recent meal. In all these cases the dark colour and fluidity of the blood indicated that the actual cause of death was asphyxia.

Discussion.

Sir WILLIAM WILLCOX said that cases of sudden death where it was difficult to find a cause at the post-mortem examination usually fell under two heads—(1) those following a hearty meal followed by vomiting and the aspiration of some of the vomited material into the glottis causing sudden death due to violent stimulation of the vagus, and (2) those from immersion in water (not drowning), in which a little water entering the air-passages produced the same effect, an effect which might be heightened by the shock of the sudden immersion of the body. He suggested that vasomotor disturbances and the filling of the great splanchnic reservoir were also of great importance.

Dr. H. DRINKWATER described a death following ethyl chloride anæsthesia of a boy aged 10. The boy had apparently recovered from the anæsthetic and

had been seen by the speaker apparently quite well. About ten minutes later he was called to the recovery room and found the boy dead. Artificial respiration and cardiac massage both proved useless. The medical man who performed the post-mortem considered death to be due to status lymphaticus, but with this he could not agree. He now reported the case because in this case as in some of Sir Bernard Spilsbury's it was noticed that the brain was very large and the skull very thin.

Mr. F. B. LEVY, who prosecuted Muchmore, inquired whether the first fight between Muchmore and Murphy could have had any effect in predisposing to the latter's sudden death from one blow struck in the second.

Dr. R. M. BRONTE reported two cases of sudden death where the cause of death was other than that which might have been supposed by the conditions in which the body was found. In another case during the administration of a spinal anæsthetic the man was dead before the needle was withdrawn, apparently from fright. It transpired that he had previously expressed to his relatives the greatest dread of operation. He had also known a case where a woman had died after trying to cause abortion in herself without having done herself injury of any sort.

Dr. F. O. MARTLEY quoted the case of a man buried for many hours in a landslide, yet able to converse with his would-be rescuers, who died as soon as a heavy plank was removed from his abdomen, as illustrating the importance of splanchnic dilatation.

Dr. SPURGIN and Sir B. SPILSBURY replied.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on March 6th, Dr. G. M. DUNCAN, the President, in the chair, when Dr. J. F. CHRISTIE gave a paper on

Tuberculosis of the Skin, with Special Reference to Lupus Vulgaris.

Dr. Christie divided the tuberculous skin affections into three classes: 1. The definitely tuberculous; where the tubercle bacillus is found in all, the classical histological appearances are present, the inoculation of susceptible animals is positive, and there is a local reaction to tuberculin. In this class are lupus vulgaris, scrofulodermia, tuberculosis verrucosa cutis, miliary tuberculosis of the skin, acute and chronic tuberculous ulcer. 2. The tuberculides; found in those who are "more or less tuberculous" and react to tuberculin. Here the histology suggests tubercle but the bacillus is only occasionally found, and it has been supposed that they are due to the circulation of toxins of tuberculous origin or to attenuated forms of Koch's bacillus. In the light of more recent knowledge, however, it must be admitted that these are forms of true tuberculosis due to the actual presence of the tubercle bacillus, but occurring in those who are putting up a good resistance to tuberculosis. The diseases in this class are thus analogous to the secondary syphilides, and include lichen scrofulosorum, the papulo-necrotic tuberculides, lupus pernio, and erythema induratum (Bazin). In these the eruptions are bilaterally symmetrical, and they tend to spontaneous cure. 3. The doubtful toxic tuberculides; including lupus erythematosus, pityriasis rubra gravis (Hebra), angiokeratoma, and psoriasiform tuberculide.

Dr. Christie then discussed the differential diagnosis of lupus vulgaris in its different manifestations—lupus simplex, exulcerans, fibroid, verrucosis, and mentioned the importance of a searching examination of the mucosa of mouth and nose as 75 per cent. of these cases present mucous membrane lesions. The diagnosis between lupus vulgaris and syphilis was particularly dealt with, and the difficulties of diagnosis in cases of these diseases co-existing were noted. The complications of lupus vulgaris were next mentioned, and in emphasising the gravity of lupus carcinoma Dr. Christie stated as his opinion that these cases were on the increase, and briefly discussed the treatment.

A full account of the treatment of lupus vulgaris was then given: general treatment by sunlight and fresh air; drugs, such as iron, arsenic, sodium morrhuate, thyroid extract, potassium iodide, tuberculin, and the arsenobenzol preparations; and local treatment by surgical measures, such as excision or curetting, freezing, X rays, Finsen light, the carbon-arc lamp, and various chemical agents, such as Brooke's ointment, acid nitrate of mercury, and trichloracetic acid. Special emphasis was laid on the necessity of long-continued treatment.

The lecture was illustrated by the exhibition of a large number of coloured plates and photographs, and by the demonstration of over 20 cases, and was followed by a short discussion.

Reviews and Notices of Books.

THE ACUTE ABDOMEN.

Diagnosis and Treatment of Acute Abdominal Diseases, including Abdominal Injuries and the Complications of External Hernia. Second Edition. By JOSEPH ADAMS, M.B., M.S., F.R.C.S., Surgeon to St. Thomas's Hospital, &c. London: Baillière, Tindall and Cox. 1923. Pp. 558. 16s.

IT is ten years since the last edition of this popular text-book was issued. The new edition has been thoroughly revised and in part rewritten, and over 20 illustrations have been added. As the author points out, more and more surgical work is being undertaken by general practitioners in cottage hospitals, and there is no doubt that a text-book of this sort will be very useful for their guidance. The first chapter is devoted to an orthodox description of the abdominal anatomy, but owing to the confines of space is of necessity very scrappy, and it is doubtful if it will serve any really useful purpose. For instance, less than a page is devoted to the lymphatics of the viscera, and the statements that the lymphatics of the stomach pass to the glands along the lesser curve, and that the rectal lymphatics end in the sacral glands are incomplete and consequently may mislead.

The clinical sections are very satisfactory. Stress is laid upon the importance of the history in arriving at the diagnosis, and the diagnostic symptoms of the individual emergencies are well and clearly portrayed, so that the work should be a very real help to those who have had but little experience of these types of lesion. The indications for treatment are also on the whole satisfactory, but a statement is twice made, in the advice given for the treatment of perforations, that the operation should be delayed if the patient is showing symptoms of much collapse. With this many surgeons would disagree, for it is now recognised that the results of operation are directly proportional to the time at which treatment is instituted. In view of recent discussions one would have hoped to see more attention paid to the value of blind cæcostomy in the treatment of acute intestinal obstruction. Although in the opinion of some authorities the treatment advocated by the author is the most satisfactory, there is a large group of cases in which a blind cæcostomy will hold out the greatest hope of saving the patient's life. It is unusual to find included in a book on acute abdominal diseases a discussion on the subject of dysmenorrhœa.

On the whole the work will be found extremely useful, and should certainly be in the hands of those who, not having large surgical practices, may suddenly be called upon to deal with an abdominal emergency. It should have and deserves a large sale to-day.

DISEASES OF WOMEN.

Fifth edition, revised and enlarged. By HARRY STURGEON CROSSEN, M.D., F.A.C.S., Clinical Professor of Gynæcology, Washington University Medical School. London: Henry Kimpton. 1923. With 934 engravings, including one colour plate. Pp. 1005. 50*s*.

OWING to the absence of the author on war service the revision of the fifth edition of this well-known work has been undertaken mainly by Dr. Hugo Ehrenfest. The book has enjoyed a considerable amount of popularity and this edition has been carefully brought up to date and is copiously illustrated and unusually complete. For example, there is included an account of the intra-uterine insufflation of gas to determine the patency of the Fallopian tubes in cases of sterility, with a full description of the technique, and the use of so-called pelvic pneumoperitoneum for purposes of diagnosis. In this some 800–1000 c.cm. of a gas such as carbon dioxide are injected into the peritoneal cavity either through the uterus and tubes, or directly through the abdominal wall, and then X ray photographs of the pelvis and abdominal cavity are taken. This is considered to be a great help in the diagnosis of such conditions as fibroids of the uterus, disease of the ovaries and tubes, especially distension of the latter, and in the recognition of the presence of adhesions in the pelvis. According to Peterson, who has done a large amount of work in perfecting this method of diagnosis, since its introduction the recognition of the exact nature of obscure conditions in the pelvis has greatly improved.

Some of the other rarer conditions of which descriptions are to be found in the book are trichomonas vaginitis, echinococcus disease of the uterus, fulminating pelvic œdema, and endometrial cysts of the ovaries. A good account with many illustrations is given of the pathology of subinvolution and chronic metritis, and the microphotographs of the differentially stained sections of the two conditions are most helpful. We notice that there is no mention of leukoplakia vulvæ in the index and find that the author describes this condition as a variety of kraurosis vulvæ. He evidently does not allow the distinction which is so commonly drawn at the present day between these two conditions or the fact that while the former appears to be a common precancerous state the latter seldom ends in that disease. The book contains a great deal of information not commonly found in text-books of gynæcology, and for this reason among others fills a definite place in the literature of the subject.

DYSENTERY IN THE FEDERATED MALAY STATES.

By WILLIAM FLETCHER, M.D., Bacteriologist, Institute for Medical Research; and MARGARET W. JEPPS, Protozoologist, Institute for Medical Research, Kuala Lumpur. London: John Bale, Sons and Danielsson, Ltd. 1924. Pp. 82. 10*s*. 6*d*.

WE have recently had occasion to draw attention to the instructive series of studies being issued from the Institute for Medical Research, Kuala Lumpur. The present volume fully maintains the standard of its predecessors. It deals with the ætiology, pathology, and treatment of dysentery as it occurs in the Malay States. The attention of the authors was immediately drawn to the remarkable contrast between the mortality-rate in Europeans and Asiatics: amongst the former two deaths from this cause have been recorded in the last three years. The mortality-rate amongst paupers, especially the half-famished malaria-infested Indian labourers, was as high as 26 per cent.; this, undoubtedly, had to be ascribed to the condition of the patients, not to any special virulence of the disease. Bacillary dysentery, then, is a disease of poverty. Taking the average weight of a healthy Tamil coolie as 112 lb., it was found that those who died had lost one-third of their body-weight, while in one extreme case the man weighed 3¼ st. Chronic malaria and atrophy of the internal organs, consequent on starvation, are held responsible for the loss of recuperative power. No evidence was obtained that malaria per se was responsible for dysenteric symptoms, or that lack of food or inability to assimilate it was responsible for beri-beric symptoms, but at the same time xerosis and pellagra occurred. As regards the ætiology, Flexner's bacillus was found to be 18 times as common as the Shiga organism. Double infections of amœbic and bacillary dysenteries were found, mostly at autopsy, in 13 per cent. of cases. As a general rule a fatal bacillary attack took place in the course of an amœbic infection. The carrier state in bacillary dysentery was found to be due to collections of these organisms lurking in ulcers, fissures of the mucous membrane, as well as in retention cysts.

It is satisfactory to note that much information recorded by British workers during the war has been fully confirmed. We may mention the employment of cytological methods, the failure of routine emetine treatment, and the vitality of the dysentery organisms in the fæces. Treatment with anti-dysenteric serum in debilitated natives was unfortunately found to be unsatisfactory, while vaccines injected appeared to be quite inert.

X RAYS.

Their Origin, Dosage, and Practical Application. By W. E. SCHALL, B.Sc. Lond., F.Inst.P. Bristol: John Wright and Sons, Ltd. Pp. 119. 5*s*.

THIS book should prove of considerable service because it gives a lot of quantitative information, and medical radiologists, as well as others interested in X ray matters, now have frequent recourse to numerical data in the current forms of therapy. The scope of the book is wide, in fact, perhaps, this is its chief weakness, for no one could treat adequately the subjects discussed in limited space. The author would, perhaps, have done well to omit that section which deals with the results of clinical treatment. Such matters can only be discussed in detail, but the author has had to fall back upon the statements of a certain limited number of people, and it is not in this way that general conclusions can be reached. In the technical and descriptive sections of the book the author is able to draw upon his own experiences, which have helped him to select most useful data and information. The first four chapters are devoted to the origin and properties of X rays, the apparatus necessary for their production and control, and the instruments in current use for measuring X rays. Then follow two chapters upon the practical applications of the rays in diagnosis and therapy. Not the least important part of the book is the collection of numerical tables which occupy the last fifteen pages. The book is well printed and illustrated by good line diagrams. It is a volume which will be useful to every radiologist.

UROLOGY.

Urologisches Praktikum. Second edition. By Prof. I. COHN, Berlin. Berlin: Urban and Schwarzenberg. 1924. Pp. 399. Swiss Fr. 11.25.

THIS manual is for students and practitioners rather than for the specialist surgeon. There are two large initial sections, one of which deals with urinary investigation methods, and the other with general symptoms such as pyuria, difficult micturition—an arrangement which is followed in a few English manuals of this class. Then follow chapters on the diseases of the several constituent parts of the urinary tract. The teaching all through, with few exceptions, conforms to English practice, and the information seems very reliable. The country of origin is labelled by the fact that much prominence is given to cryoscopy and indigo-carmine injections in investigating renal function. Phenolsulphonephthalein is said to have no advantage over indigo-carmine, but it is surely more easily estimated quantitatively. The urea-concentration test as we know it is not mentioned. It is to be noted that the author has obtained good

results from a modified Bottini operation in certain selected cases of enlarged prostate. This section on the enlarged prostate is systematically treated. The author regards pyelography as dangerous, but practically all risk has been eliminated by modern technical methods. He finds air distension of the bladder a useful diagnostic method, and it might certainly be used more often in this country with advantage. There are a number of very truly reproduced coloured endoscopic pictures of bladder and urethra.

The book can be recommended as a reliable guide to the inquiring student or practitioner.

QUANTITATIVE CHEMICAL ANALYSIS.

Twelfth edition. By FRANK CLOWES, D.Sc. Lond., Emeritus Professor of Chemistry in University College, Nottingham; and J. BERNARD COLEMAN, A.R.C.Sc. Dub., Head of the Chemical Department, Chelsea Polytechnic, London. London: J. and A. Churchill. 1924. Pp. 576. 18s.

IN something the same way as the name of Gray at once occurs to the mind when books on human anatomy are mentioned, this classical volume is associated closely with the subject of quantitative chemical analysis. From the publication of the first edition in 1891 to the present time it has been regarded as a standard work on the subject. The first chapters are devoted to descriptions of balances and how to use them; then follows a detailed practical description of all the well-known pieces of apparatus used in the subject. After these necessary preliminaries have been mastered by the student, he is taken through a complete course of analysis, the estimation of almost every inorganic element being described. The analysis of fats, oils, tannins, and soaps is dealt with, and there is a very fine section on the ultimate analysis of organic compounds. The chapter on gas analysis is rather out of date, and it is somewhat surprising that no account of Haldane's methods are given.

The new edition will be welcomed by many, and it is certain that the work will retain its high place in the literature on quantitative analysis.

JOURNALS.

THE BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXI. January–March.—In an article on "Idiopathic" Hypertrophy of the Bladder, by Dr. A. Dingwall Fordyce and Dr. Norman B. Capon, with a pathological report by Prof. Ernest Glynn, the writers review the literature and record two illustrative cases in children, aged 12 and 16, in which there was no tangible or obvious cause for the condition found during life or post mortem. During life the clinical picture resembled that of chronic interstitial nephritis in the large flow of albuminous urine and the marked renal inefficiency. On physical examination a globular hypogastric mass was found which was the hypertrophied bladder. The necropsy showed hypertrophy and dilatation of the bladder and dilatation of the ureters and renal pelvis, with cyst-like dilatation of the kidney tissue. The condition resembled pyloric stenosis, idiopathic dilatation of the œsophagus, and Hirschsprung's disease, for all of which there is probably some neuropathic basis. The paper is accompanied by numerous excellent macro- and micro-photographs.—Dr. H. S. Hutchison and Dr. Grace Stapleton contribute the first part of a paper on Late Rickets and Osteomalacia, in which they discuss the clinical position of puerperal osteomalacia, their conclusions being as follows: Pregnancy does not cause changes differing in any way from those occurring apart from pregnancy. There are the same incidence and occurrence, the same clinical signs, and the same radiological picture, irrespective of the occurrence of pregnancy. Osteomalacia may occur in men, so that pregnancy cannot be regarded as a necessary ætiological factor, but merely as a contributory factor.—Dr. Grace H. Anderson also contributes the first part of a paper on the Calcium and Phosphorus Content of the Blood in Normal and Rachitic Children, in which she concludes that though the blood-calcium is slightly more variable in rachitic than in normal children, the variability has no diagnostic or prognostic value, so that a study of calcium values alone is unlikely to prove of much assistance as an indication of cause or treatment.—In a paper entitled Anæmia with Enlarged Spleen in Infancy: "Infantile Splenic Anæmia," Dr. Grenville W. St. C. Ramsay reviews the literature and records his observations on 45 cases, which are classified as follows: (1) 27 showed all the features which are generally considered essential to justify a diagnosis of infantile splenic anæmia, such as anæmia, degenerative and regenerative forms of red cells, myelocytes in the peripheral blood, and enlargement of the spleen. (2) In 12 cases the blood picture was complete except for the presence of myelocytes. The spleen was enlarged in all. (3) In six cases the blood was typical, but there was no enlargement of the spleen. The writer concludes that the so-called infantile splenic anæmia is not a disease *sui generis*, but is a form of simple secondary anæmia.—Dr. Robert Hutchison and Dr. Gladys M. Wauhope report a case of Precocious Puberty in a girl aged 3½ years, in whom menstruation began at the age of 18 months. The period lasted for two or three days, and returned at regular intervals of 28 days, except on three occasions, when the interval was exactly two months. After the child's third birthday the intervals became irregular and of longer duration. Pubic hair was noticed at the time of the first period. The breasts were well formed, but no definite date could be given for their enlargement. On abdominal and bimanual examination under an anæsthetic both ovaries were palpable and of normal size. X ray examination of the skull showed no sign of tumour or other abnormality, but skiagrams of the skeleton showed a bony development usually present about puberty. The writers discuss the causes of precocious puberty—viz., hypernephromata of the suprarenal cortex, tumours of the pineal gland, and tumours or hyperplasia of the gonads, and came to the conclusion that the precocity in their patient was due to ovarian hypersecretion.—The abstracts from current literature are devoted to diseases of the blood.

New Inventions.

AN IMPROVED ABDOMINAL SUPPORT.

THE appliance here illustrated has been designed to give an efficient support to the lower abdomen, and to carry the weight of the abdominal viscera in intestinal stasis, enteroptosis, and lower abdomen post-operative cases, and at the same time to be comfortable to wear. The support consists of a single leather-covered and padded aluminium front and back plate with rubber pneumatic cushions, connected

by two lateral steel springs, hinged to, and sprung, or levered about, the lateral edges of the back plate, the right spring being detachable in front. The advantages are: (1) No pressure is exerted anywhere except on the front and back plates. The springs barely, or only lightly touch the body; this result is obtained by the leverage on the springs over the edges of the back plate when the support is in position on the body; this leverage also practically converts the appliance into a single-spring support, and so

necessitating a lighter spring than usually employed. (2) The back plate is centrally placed, and is padded to avoid pressure on the spine, and cannot press upon or bruise the gluteal muscles or large sensory nerves crossing the buttocks. (3) The attachment and release is easy to manipulate and under the direct view of the wearer. A simple partial release is fitted, easily adjusted without undoing the clothing, making it comfortable to sit or recline for long periods. (4) The appliance is light in weight and has 2¼ inches of adjustment.

The support is made and supplied by Messrs. W. H. Bailey and Son, 45, Oxford-street, W.

The Conduct of Medical Practice.

A Series of Articles by Experts dealing with the Difficulties Encountered in Professional Life and How to Meet Them.

XIII.

LEGAL ASPECTS OF "DICHOTOMY."

BY A SOLICITOR.

Guise: "He that will be a flat dichotomist . . .
"Kill him!"
Ramus: "Oh, good my lord,
"Let me but speak a word."
—Marlowe, *Massacre at Paris*, Act I., Sc. 8.

IN a recent issue[1] was recorded the unanimous condemnation of fee-sharing by a meeting of consultants and specialists in a large provincial centre. The practice of "dichotomy," or secret fee-sharing, between a consultant and the general practitioner who has called him in, has medical aspects on which I am not competent to write. The practice has also legal aspects of a serious kind. Naturally the facts differ in each case, but we will suppose that a patient is attended by a general practitioner who advises an operation or a consultation, that the patient accepts the advice and leaves it to the practitioner to arrange for the services of the operating surgeon or consultant at a particular time, place, and fee, and that the operating surgeon or consultant, on being paid his fee, hands part of it over to the practitioner behind the patient's back. At once the following legal consequences result. If it be right to speak of the practitioner as having been the patient's agent (a point which will be returned to presently) the agent has taken a surreptitious profit in the course of his agency. An agent must not enter into any transaction in which he has a personal interest in conflict with his duty to his principal, unless the principal is fully informed and consents. If the patient is unaware of what is going on behind his back, he may, when he finds out the facts, insist that the practitioner (as his agent) shall account to him for the secret profit he has received. The agent must hand it over to the patient who otherwise can bring an action for the return of the money.

Possibly the practitioner and the consultant would plead in defence that such fee-sharing was a trade usage. For this plea to succeed, the court would have to be convinced that the practice was reasonable and that it was not only common but general. There is little doubt that the practice would not be held reasonable, for it alters the nature of the contract between patient and consultant without the knowledge of the former, and it gives the agent an interest in conflict with his duty to his principal.

Civil or Criminal Proceedings.

Thus far the reference has been to the legal aspect in civil proceedings. But dichotomy has a criminal aspect too. Under the Prevention of Corruption Act of 1906 "if any agent corruptly accepts or . . . attempts to obtain . . . any gift or consideration as . . . reward for showing any favour to any person in relation to his principal's affairs or business," he is guilty of a misdemeanour punishable with a fine up to £500, or imprisonment up to two years' hard labour. Might not a jury be asked to consider that the practitioner is showing favour to a particular consultant if he recommends to the patient, and procures the services of, one from whom he has the expectation of receiving, and perhaps on similar occasions previously has actually received, a kind of secret brokerage or commission? A corresponding offence under the Act is committed by anyone who gives money to the agent in these circumstances. Finally, it might be possible to frame an indictment under another part of the Act if the giving or showing of a receipt for the consultant's full fee could be proved to have deliberately misled the patient into the belief that the full fee had been properly received and represented a bona fide transaction.

The crux in the legal position is the question whether the practitioner acts as agent of the patient in obtaining the services of, and making the necessary arrangements with, the consultant. This is a question of fact. Agency may be inferred from the conduct of the parties. An agent is a person employed to bring the employer into legal relations with a third party. It is true that, in authorising his doctor to obtain for him the services of a consultant, the patient is asking the doctor to do something for him gratuitously. But dichotomy puts an end to the gratuitous element in the transaction. Moreover, where the transaction is gratuitous, the only legal difference is that the parties may have no legal remedy if the transaction is not carried out at all—i.e., if the consultant's services are not obtained. As soon as the transaction is under way and the patient meets the consultant, the question whether the agency was gratuitous or not becomes immaterial. Again, the patient may pay the consultant direct, but that fact does not negative the inference of agency. And, at any rate in the criminal statute which we have quoted, there is a wide interpretation of agency. An "agent" is defined as including "any person employed by or acting for another." The position of a defendant would be even more serious in a panel case, for the amending Act of 1916 provides that if money has been paid to, or received by, a person in the employ of a Government department or a public body, the transaction is presumed corrupt unless the contrary is proved.

No Legal Analogy.

No analogy from the legal profession can be craved in aid. A busy barrister sometimes (but by no means always) gives a part of his fee to another barrister who has "devilled" a case for him. Here there is no element of agency, for the recipient had nothing to do with the engagement of the barrister's services. If one could imagine a solicitor employing a barrister at a fee of 50 guineas with a secret understanding that the barrister should hand 5, 10, or 20 guineas back to the solicitor behind the client's back, or if one can imagine dichotomy between a general practitioner and the chemist who makes up his prescriptions, one gets a truer analogy. The gist of the offence is the improper secrecy. The effect of secret fee-sharing on the relations between the medical profession and the public is easily imagined. It must inevitably suggest that the consultant's fees are artificially and unjustifiably raised in order to provide a margin to cover the secret commission, that the patient is deprived of the genuinely disinterested advice he expects from his medical attendant, and that members of the medical profession are not above petty conspiracy to hoodwink the persons who pay for their services. It is fair to say that proceedings under the Prevention of Corruption Act are seldom successfully taken, owing to the difficulty of obtaining sufficient evidence. But for a medical man even to be acquitted on such a charge would hardly be edifying, and, if there be any doubt about the law, a practitioner will hardly desire to give his name to a leading case on the subject.

THE LANCET.

LONDON: SATURDAY, MARCH 29, 1924.

MEDICAL EDUCATION IN CAIRO.

THE Royal School of Medicine at Cairo, formerly known as the Egyptian Government Medical School, and still better as the Kasr-el-Ainy Hospital and School, is an institution with a long and chequered history. Founded in Napoleonic times, afterwards fostered by MAHOMED ALI, it has languished from time to time, to revive under some foreign tutelage, which has been at various times, French, Italian, and British. Under the last two British directors, Dr. H. P. KEATINGE and Mr. OWEN RICHARDS, it has reached a high state of efficiency and developed into an important centre for medical education, being the only one in Egypt. The School is under the direct control of the Minister of Education, but the Under-Secretary of State for Public Health is also concerned in the administration of the hospital. The entry is limited to a hundred new students each year, selected from the successful candidates at the examinations for the secondary education certificates in science. The curriculum for the diploma of the Royal School of Medicine at Cairo has hitherto been approved by the Conjoint Board of the English Royal Colleges, who send a visitor to the examinations, which are conducted in English. The diplomates of the Royal School of Medicine are allowed to proceed direct to the final examinations of the Conjoint Board when they come to this country, a privilege which has been extensively used by Egyptian practitioners coming here to work for higher qualifications. The school at Cairo is well equipped and is staffed by a number of professors, who until recently have been mostly of British nationality with Egyptian assistant professors and demonstrators, although the chair of parasitology was formerly occupied by a German, Prof. ARTHUR LOOSS, who made very distinguished contributions to the literature of his subject. The clinical material at the hospital is almost unrivalled. There is an average daily attendance of nearly a thousand patients in the various out-patient clinics. Unfortunately, the hospital buildings are old and incapable of further extension or adaptation, with the result that the arrangements in the hospital are cramped, unsatisfactory and unworthy of the school. We understand that plans were in preparation for a new and up-to-date hospital near the school, but for some reason this scheme has not yet been put into execution. The present flourishing state of the school is without doubt due to the good work done by the English professors in the school and hospital with the loyal coöperation of their Egyptian colleagues, and special attention is given in the curriculum to subjects of importance in Egyptian practice, notably ophthalmology, parasitology, forensic medicine, and public health. A large proportion of the successful students enter the Government service, so that their familiarity with these subjects becomes of national importance.

Some time ago clinical units were established in medicine and surgery, and at the time Prof. H. B. DAY and Prof. R. V. DOLBEY are whole-time directors in charge of these units respectively. With their coöperation we have published in THE LANCET recently a number of original papers from the staff of the Kasr-el-Ainy Hospital showing what use is being made of the valuable material there available for research. The work of Prof. DAY [1] in the treatment of ankylostomiasis and bilharziasis is of great importance and has formed the basis of a concerted effort to deal with these parasitic infestations, from which it is calculated that at least 70 per cent. of the fellaheen suffer. His articles are well worth careful study as they are clear and practical, giving full details of the methods employed. An Egyptian lecturer on parasitology, Dr. KHALIL, has now been appointed, and he is engaged in research into the numerous problems presented by parasitic diseases in Egypt. Mr. F. C. MADDEN, the professor of surgery in the School, has published a valuable text-book on the Surgery of Egypt, which is admirably illustrated and covers well the field of surgical disease in Egypt.[2] We have tried in the contributions from the School published in our columns to bring these and other activities clearly before our readers. Among the papers on surgical subjects, which have been published in our columns, we may mention that of ALI BEY IBRAHIM on bilharziasis of the ureter,[3] and that by Prof. DOLBEY and IBRAHIM FAHMY on bilharzial papillomatosis of the rectum. In the latter the treatment of the condition by the operation of removal of the whole tube of mucous membrane of the rectum is described and illustrated. Probably few practitioners in this country have seen a case of hydrophobia. The paper by Prof. DOLBEY and Dr. ABDULLAH EL KALIB on hydrophobia in Egypt gives a striking account of this disease as seen in Egypt. We may also refer to the paper on the incidence of cancer in Egypt published in last week's issue of THE LANCET by Prof. DOLBEY and Mr. A. W. MOORO, as it contains some suggestive observations and indicates that there is scope for some original work on this disease in that country. The various papers to which we have referred show that the importance of original work and research is being recognised at the Cairo School. We may venture to hope that work of this kind will be encouraged there as it should serve to enhance the reputation of the school.

The alteration in the national status of Egypt and the recent political changes will doubtless have their repercussion upon the Royal School of Medicine. At present, the director, the two whole-time clinical professors, all the professors on the early subjects, and the senior member of the visiting staff in the three branches of medicine, surgery, and obstetrics are of British nationality; as until recently was also the professor of ophthalmology. Changes are already in progress, and there is no doubt that the policy of the Egyptian Government will be similar to that followed in other of the Government institutions—namely, the replacement of British members of the staff by Egyptians. No one denies the danger that such alterations may be made too quickly. Sudden changes are frequently disruptive and disorganising. The present state of the School is one of promise, provided it is equipped with an adequate hospital and guided wisely during its period of transition. Given such conditions it should develop into the most important centre for medical education and research in the Middle East. A too narrow interpretation of national aspirations might have the reverse effect and restrict the school to a very limited field with the loss of its recently won European status and recognition.

CLINICAL RESULTS IN DEEP X RAY THERAPY.

SINCE the action of the X rays upon new growth cells was first observed continuous efforts have been made to treat successfully various forms of cancer. The degree of success has varied with different workers, and up to quite recently the work has been empirical in nature. Within recent years the treatment of cancer by X rays has received fresh stimulus from the published results of continental workers, notably those working at Erlangen; and all over the world radiologists and clinicians have tried to repeat these results, using in many instances the same form of apparatus and tubes, and as nearly as possible the same technique as that described by the continental writers. The question of technique is an important one, for the original Erlangen technique required for its execution an infinite amount of detail work; and it has been argued that the absence of any one of these details might reasonably be accountable for failure. It is obvious that if a test of the method is to possess any value the carrying out of the treatment must be done in exactly the same way as in the original.

This has not always been done. The discussion at the Royal Society of Medicine on March 21st, and reported on p. 649 of our present issue, was opportune in that, before a large gathering of radiologists and clinicians, the results of treatment received full consideration; a number of workers who had followed the original technique gave their experiences and results obtained in the treatment of a large variety and number of cases of malignant disease. There can be no doubt that the hope of curing cancer by the more intensive treatment, made possible by the production of more powerful apparatus and tubes, has induced many workers to enter the field, and to treat cases sometimes with greater enthusiasm than judgment, the consequence being that disastrous results have before now ensued. In this connexion the important point was made by several of the speakers that only selected cases, in which a chance of relief or cure could be looked for, should be subjected to the great physical strain of a complete intensive treatment; and it was frankly admitted that many of the cases which had undergone treatment in the past were quite unsuitable on account of cachexia, or a relatively low blood count. Brief reference only was made to the undoubted danger of over-exposure and its sequelæ, X ray burns and asthenia. The question of the single large dose and the divided dose in the treatment of carcinoma was fully discussed, arguments being advanced on both sides. There is little doubt that the divided dose, even if it has to be carried somewhat further in the aggregate than the single dose, is preferable, because of the lessening of the strain upon the patient. In actual practice it is found that results can be obtained which are quite as good as any so far produced by the single large dose.

After careful consideration of the large amount of clinical material available, the fact stands out clearly that a great advance in technique has been made in recent years in the treatment of malignant disease. Thus it would be unfortunate if the value of this advance should be lessened by an undue magnification of the failures in the results obtained by over-enthusiastic and possibly inexperienced workers. Such a sequence appears always upon the advent of a new technique, or the improvement of an existing one. The crucial test of radiotherapeutic measures will inevitably be the measure of the success obtained in the treatment of cancer; and in this direction it is obvious that the test is a severe one, particularly as up to the present in this country, at all events, the failures of other methods are handed over to the radiologist as a last resort. The critical test would require to be applied not to a hopelessly inoperable case of cancer, but to one which offers an equal chance of cure to either method of treatment. Nor should the radiologist alone be responsible for the case. A selected team of experts should watch the progress of the case during treatment. The observations of such a team working in accord would be of the greatest possible value in our estimate of the whole position. In radiation we possess no specific cure for cancer. Until we know more of the intricate changes in cellular growth and the changes occurring in morbid conditions it will be useless even to contemplate the possibility of a specific cure. A great deal of experimental work must yet be done before the biological processes of cell growth and the response to radiation can be understood.

The needed organised research should include the services of the clinician, the biologist, the biological chemist, the morbid histologist, and the radiologist. The assistance of the physicist will also be required for the elucidation of problems of physico-biological interest. The patient must be the first consideration in all attempts at cure by radiation or allied measures. Treatment should be carried out on rational lines, which are evolved from a consideration of physiological and pathological processes. If a very long exposure is contemplated, then all steps should be taken to ensure that the patient is in a fit condition to stand the strain. A careful consideration of the pathological processes at work, the condition of the tumour, the type of cell composing the bulk of its structure, and the state of the surrounding tissues, will in a large number of cases rule out at once any hope of a cure: the treatment must then become palliative, and in this group there is a large field for the radiotherapist. In an inoperable case of cancer combined treatment is the most rational procedure. The diathermy current will be found to be most useful in any such combination, while radium and X rays may be used singly or in combination. Fresh air, good food and tonics help toward the improvement of the patient's condition, aiding the action of radiations often to a marked degree. If treatment be carried out along these lines it will be found that occasionally an inoperable tumour will be so reduced in size that the possibility of operation can be considered; still more rarely a tumour entirely disappears and the patient is restored to normal health. The choice between surgical removal and radiotherapeutic measures, in a case of early cancer, does not at the present time exist; with average risks from the operation, there is no doubt that surgery is preferable, and most experienced radiologists are in agreement on this point, although at the moment it deprives them of the opportunity of applying what we called above the critical test. The value of prophylactic treatment was discussed by several of the speakers at the discussion on March 21st; this, in our opinion, should always follow surgical removal of malignant growths. Cases could be quoted, and are quoted, in which recurrence has taken place very soon after the commencement of prophylactic X ray or radium treatment. This may be difficult to explain, but the fact that a very large number of cases have recurred soon after operation is not an argument against operation in the majority of cases. A more cogent fact is that superficial recurrence has been temporarily cured in a con-

siderable percentage of cases treated by X rays, and this in itself is sufficient ground for continuing their application.

THE OPERATIVE TREATMENT OF CANCER OF THE LARYNX.

OPINION has not yet definitely crystallised on the subject of the most satisfactory methods of removal of cancer of the larynx in its various stages and in the various degrees of involvement of the organ. For most forms of extrinsic growth, and for intrinsic growths which have become extensive, it is generally agreed that total laryngectomy offers the only hope of cure; but a considerable difference of opinion still exists as to whether cases of early cancer confined to a vocal cord, or even to a part of it, should be submitted to laryngectomy, or whether in such cases the far less mutilating operation of thyrotomy, or laryngofissure, is sufficient to provide a really good prospect of eradicating the disease. The operation of thyrotomy, which was largely developed by the work of SEMON and BUTLIN, has been far more in favour in this country than abroad. Sir STCLAIR THOMSON has reported a series of 38 cases with one death from operation and but nine recurrences, and in America CHEVALIER JACKSON, in a series of 42 cases, had no immediate mortality and only five recurrences. Such results are surely as good as those for cancer operations in any part of the body, and, when one considers that the voice is usually very fair and that no other disability results, it might be expected that the question would have been definitely settled in favour of this operation.

In an interesting article in the last number of the *Journal of Laryngology* [1] Dr. J. E. MACKENTY, of New York, prefers a strong plea for the operation of laryngectomy for cases of early laryngeal cancer. Since 1917 he has rejected all cases of extrinsic cancer for the good reason that, during several years of surgical effort, he had not succeeded in ultimately saving one. But it is the question of the early cases which we are here considering. Three of his cases were in a stage so incipient that the mobility of the involved cord was normal in two and but slightly impaired in the third; the neoplasm in all three occupied from one-quarter to one-third of the extent of the cords, leaving apparently normal tissue both in front and behind the growth. Nevertheless, they were submitted to laryngectomy. Dr. MACKENTY is quite convinced that the opinion of the majority would have condemned the radical procedure in these cases, "so wedded are laryngologists to conservatism in the treatment of laryngeal cancer"; and he is certain that careful microscopic study of the three larynges gave conclusive evidence that no partial operation would have saved the victims from recurrence. In two the areas of malignancy extended into the angle of the anterior commissure, and in the third it extended in both directions, stopping just short of the arytenoids and the anterior commissure. In contradistinction to this, Sir STCLAIR THOMSON states in his book on "Diseases of the Nose and Throat" that good results are even obtainable if the disease has spread across the anterior commissure, so that all one cord and a portion of the other have to be excised; and he gives an illustration of such a case treated by thryotomy and free from recurrence eight years after operation. So that it is doubtful whether Dr. MACKENTY'S proof is really conclusive. The operative results of his laryngectomies are very good, with a surgical mortality of less than 2½ per cent., and he lays stress on the fact that many of his patients are leading useful and strenuous lives in business and professional careers.

In the same issue Mr. J. S. FRASER and Mr. DONALD WATSON, of Edinburgh, report on 14 cases of intrinsic cancer of the larynx. They conclude that thyrotomy is only indicated if the cord is still fairly movable and if the growth does not transgress the anterior commissure or reach the vocal process, and they point out the tendency to infiltrate between the thyroid and cricoid cartilages. In the larynx, as elsewhere, the chief hope at present lies in early diagnosis and early operation, and we would endorse the latter authors' conclusion that "They would like to see a notice in large type sent to all general practitioners as follows: Every case of hoarseness which lasts more than a few days should have the larynx examined. If you can't do it yourself, send the patient to someone who can."

[1] Journal of Laryngology and Otology, February, 1924.

THE AVAILABILITY OF PHYSIOLOGICAL KNOWLEDGE.

THE present plethora of scientific progress has its difficulties as well as its gains. It is by no means easy, and is becoming progressively harder and harder, for a man to gather in from all the varied lines of advance the items which are germane to his particular interests. And it is often from these side lights that he gets most illumination. Men like SYDNEY RINGER could know all about physiology as well as clinical medicine. Indeed, such a possibility was open to any industrious and retentive intelligence up to about 25 years ago. But no one could do it nowadays; it would be an appreciable part-time job for anyone to survey the contents of the journals of the sciences, which, though immediately connected with medicine, have not yet attained their majority. We print in another column a letter from Dr. T. LUMSDEN putting forward cogently the difficulty of securing that the progress of anatomical and physiological knowledge shall be reflected in any clinical work to which it may be applicable. The difficulty is a real one; many of our readers are possibly unaware of Dr. LUMSDEN'S own investigations on the location of the various respiratory centres in the medulla and pons which have appeared during the last 12 months or so in the *Journal of Physiology*. And in the end the difficulty is a very old one, for it is the difficulty of knowing all about everything.

Nevertheless, a good deal might be done to diminish the difficulty. Anatomists, physiologists, biochemists, geneticists, and so on, can of their own initiative do little; they do not know what particular topics are of interest to the clinician, and if they have been duly attentive to their own studies they will find that in the 10 or 20 years which have gone by since their own experience of the wards—if, indeed, they have had such experience at all—clinical problems have greatly changed. It must rest with the clinician to extract for himself what is of moment to himself; he alone knows the problem which interests him and can appreciate which pieces of information are of value in that particular connexion. How to know what information is available is the real difficulty. Dr. LUMSDEN suggests that the clinical journals might publish more in the way of reports on scientific progress, and that the Royal Society of Medicine might have sections for the ancillary medical sciences. Both projects would probably be useful, though some might doubt whether the people concerned will put up with any more meetings than are held at present, and it is possible that a section of physiology, for example, would be frequented only by physiologists. On the whole we should attach more importance to improvements in the available current literature. The new American journal *Medicine* provides admirable reviews by experts which deal, despite the title, almost entirely with what is ordinarily called physiology or pathology. The *Physiological Review* again covers in much the same way topics which, mostly physiological, range into such medical subjects as the ætiology of rickets. It should certainly be possible for the clinical journals to report to their readers the titles of the monographs which appear in these two most useful publications; the originals are available at the libraries if they happen

to be wanted, and some, at any rate, of the papers in *Medicine* are republished and may be bought separately. In rather a different category come the abstracting journals with short accounts of original papers only roughly classified. The most obviously useful to English clinicians is *Physiological Abstracts*, which appears every two months; an hour would suffice to run through the pages and learn if mention is made of anything of particular interest to a particular reader. The trouble about this admirable magazine, skilfully guided through its early years by the zeal of Prof. W. D. HALLIBURTON, is that it will come to an end next year unless it receives a measure of support more equivalent to its virtues; perhaps a wider circulation among clinical workers would be enough to save it.

These are specialised publications which in their several ways would help to realise Dr. LUMSDEN'S ideal if clinicians are keen enough to keep in touch with them. And other branches of the natural sciences have journals more or less in correspondence. No one can be on all the advancing fronts simultaneously, and it would need a good deal of assiduity to apprehend the summaries of what is going on in each place. But an earnest worker can always do his best.

Annotations.

"Ne quid nimis."

JONNESCO'S OPERATION FOR ANGINA PECTORIS.

SURGEONS, in devising new operations, often provide anatomists and physiologists with fresh and very practical problems. Why should Jonnesco's operation of removing the middle and lower sympathetic ganglia of the neck relieve the pain of angina pectoris? A paper by Mr. R. C. Shawe, which we publish this week, helps us towards an explanation. He has discovered that in the sympathetic twigs which join the vagi and recurrent laryngeal nerves at the junction of neck and thorax there are medullated nerve fibres of various sizes. The fibres of large size he has followed to the cardiac and aortic plexuses, and rightly infers that they must serve as channels for afferent or sensory impulses concerned in the reflex control of the heart. If we suppose that these lower cervical sympathetic twigs are the pathways by which abnormal impulses reach upper dorsal centres of the cord and there give rise to anginal radiations, then we have a satisfactory explanation of the rationale of Jonnesco's operation. The same twigs apparently serve as pathways for secretory fibres to the thyroid gland. Mr. Shawe's communication will serve to remind the rising generation of medical men how much there is still to be done in unravelling the structure and function of the great sympathetic plexuses of the thorax and abdomen and how practical the results are which will issue from investigations of this kind. Mr. Shawe acknowledges indebtedness to Prof. J. S. B. Stopford, the occupant of the chair of anatomy in the University of Manchester, who has demonstrated how successfully anatomical and clinical methods of research can be combined. Dr. James Ross, the founder of the neurological school of Manchester, was a physician; his work was continued by a surgeon—the late Sir William Thorburn; and in continuing and furthering researches into the structure and nature of the nervous system the anatomist has returned to his proper rôle in medicine.

IMPROVEMENTS IN OPTICAL EQUIPMENT OF OTO-LARYNGOLOGISTS.

The last number of *Acta Oto-Laryngologica* (vol. v., fasc. 4, 1924) contains ten original articles, seven of which deal with improvements in the optical equipment of the oto-laryngologist. Austrian, French, German, and Swedish specialists have written these papers which show how much the recent work of Gullstrand, Holmgren, and others has done to facilitate the examination at close quarters of objects hitherto imperfectly seen in the respiratory passages and ear. It is a very remarkable fact that though binocular vision was much appreciated in the 'sixties and 'seventies of last century, its value came almost to be forgotten, and laryngologists were satisfied during the past half century to use only one eye at a time. The average housewife, familiar with the difficulties of threading a fine needle with the help of only one eye, could have told them how badly they were handicapped. According to Dr. Carl von Eicken, of Berlin, the inventor of the binocular system of lenses for throat, nose, and ear specialists, many physicians remain under the impression that they are using both eyes when examining the interior of the ear, nose, and throat. One of the most interesting optical instruments described is the relascope, which enables the wearer to enjoy binocular vision, and two other observers, one on each side of the wearer, to look through its side windows and to see with monocular vision the same object that the wearer of this instrument is seeing and operating on. The teaching value of such an instrument is obvious. Other instruments described are the spectacle magnifier of Gullstrand, a binocular telescopic lens, an otomicroscope, and glasses to protect the operator's eyes from spurting blood and pus. A paper by Prof. G. Holmgren, of Stockholm, shows to what practical purposes recent improvements in optical instruments can be put in this field. With the help of a binocular microscope, he has recently operated on four cases of otosclerosis, the labyrinthine capsule being incised under the microscope with a degree of precision which would have been impossible without such control. In three of the four cases his attempts to make an artificial window in the labyrinthine capsule achieved a certain degree of success, auditory perception being improved, and no permanent injury inflicted on the neighbouring structures. Such operations for otosclerosis must, in Prof. Holmgren's opinion, be still regarded as in the experimental stage, but it is already evident that the prospect of their becoming perfected is greatly enhanced by the important advances recently made in optical instruments.

AUTOPSIES AND DEATH CERTIFICATION.

THE scientific value of a death certificate unsupported by the evidence of a post-mortem examination was the subject of a recent discussion[1] at a meeting of the Medical Society of Berlin, and, as might have been anticipated, the unconfirmed clinical diagnosis was severely criticised. One of the speakers, Dr. Lubarsch, deplored the fact that the present campaign in favour of economy was invading even the post-mortem room, and he insisted that the curtailment of post-mortem examinations could not be regarded with equanimity by any who were interested in public health. To show up the incorrectness of the Prussian mortality statistics not based on a post-mortem examination, he compared them with certain necropsy statistics. According to the Prussian mortality statistics, there were 922,350 deaths in 1920, of which 52,476, or 5·6 per cent., were due to cancer, and 5531, or 0·6 per cent., were due to other new growths. In only 5 per cent. of all the deaths had a post-mortem examination been conducted, and among the necropsies performed in the two-year period 1920–21 in the hospitals throughout Germany, there were 8301 cases, or 9·7 per cent., showing carcinoma, and 683, or 0·8 per cent., showing sarcoma. The incidence of malignant disease was thus shown to be much higher by the evidence of post-mortem examinations, than by that of uncontrolled clinical diagnoses. Even when the cancer was superficial, it was not infrequently overlooked by the clinician, and 4·93 per cent. of the 1297 cases of external cancer were undiagnosed during life. In another 3·24 per cent.

[1] Deutsche medizinische Wochenschrift, Feb. 15th.

the site of the disease was wrongly located, and 10·86 per cent. of the cases of superficial sarcoma were not recognised as such. Of 5908 cases of internal cancer, 17·17 per cent. had escaped diagnosis altogether, and in 15·04 per cent. the disease had been wrongly located. Thus diagnostic mistakes were made in 32·21 per cent. of the cases of internal carcinoma, and in the case of internal sarcoma, this mistake-rate was still higher, being 44·7 per cent. Of 450 cases of pulmonary and bronchial carcinoma coming to necropsy, 240 had been wrongly diagnosed. As was pointed out by Dr. Benda, who took part in the discussion, post-mortem examinations are not only of value in the compilation of truthful statistics, but also in forming a just opinion in traumatic cases, and in adjudicating on pension and insurance claims. As another speaker pointed out, necropsies discourage ill-considered diagnoses. The time when a necropsy is regarded as an unavoidable preliminary to burial may still be far distant, but when it comes it will assuredly witness a more careful and skilled physical examination of the patient than is usual at present.

THE HOSPITAL WORK OF THE SALVATION ARMY.

COMPARATIVELY little appears to be known by the general public of the medical and hospital work which the Salvation Army is doing in various parts of the world. In a recent issue of the *War Cry*, the official organ of the Salvation Army, an account is given of some of the activities carried on at home and abroad by means of the international medical service organised by this body. In Great Britain the medical work appears to have grown directly out of the maternity homes which were opened in most of the great cities for the benefit of unmarried mothers. In response to public demand these facilities were extended, and lying-in hospitals for all classes of women were subsequently founded in London and the provinces. The Mothers' Hospital at Clapton, which was opened in 1913 by Princess Louise, Duchess of Argyll, is perhaps the best known of these institutions. The value of the work carried on here may be gauged by the fact that during 1923 1129 births took place in the hospital, and 1493 under the direction of the Mothers' Hospital district visiting staff.

The medical work in *India* is represented mainly by three large hospitals—the Catherine Booth Hospital in Nagercoil, Travancore, the Emery Hospital in Gujerat, and the Thomas Emery Hospital in Moradabad, United Provinces. From the Emery Hospital a medical motor-van goes out among hundreds of neighbouring villages, taking skilled surgical relief to thousands of ignorant villagers. Two hundred cases weekly are treated by this means alone; while in many other centres are village dispensaries from which simple remedies and appliances are distributed. During 1922 51,254 patients were treated by the Salvation Army in India, and 451 major and 1989 minor surgical operations were performed. The *Dutch Indies* are well served by the Salvation Army, one outstanding piece of work being that carried on at the William Booth Eye Hospital at Semerang under the direction of the well-known Danish ophthalmic surgeon, Dr. W. A. Wille. During a recent year there were no fewer than 43,650 consultations at this institution. Another branch of work, no less valuable, is connected with the four leper settlements founded by the army in the Dutch Indies where leprosy is very rife. A maternity home has been established at Soerabaja, attached to which is a children's clinic and an institution known as a policlinic at which 47,128 patients were treated during 1922. A new hospital which will accommodate some 80 patients is now in course of erection at this centre. Apart from these institutions there are a number of medical stations in Java and elsewhere at which ailments are treated by simple remedies administered by non-medical workers.

In *China* plans are being laid for the erection of a large hospital. *Japan* boasted the only Salvation Army tuberculosis sanatorium in the world, 351 patients having been treated here during 1922. Medical work, however, received a severe set-back through the earthquake and fire on Sept. 1st of last year. The hospital in Tokio was completely destroyed, but within a few hours of its destruction a temporary hospital for expectant mothers had been established among the ruins. In *Cape Town* the William and Catherine Booth Memorial Hospital for Women and Children, the first of its kind in the Union, has proved a boon to the people. A training school for midwives and nurses has been incorporated with it, and there is a widespread demand for the services of students who have received their training here. Hospitals and maternity homes are in operation in many centres throughout the *United States*, dental clinics also being common. In *Canada* the Grace Hospital for Mothers, at Winnipeg, has over 200 beds which are always full. More than 1400 births took place there during 1922. Edmonton and Halifax also possess well-equipped hospitals. In *Australia* representative institutions are the Bethesda Hospital, Melbourne, and the McBride Maternity Hospital, Adelaide.

While there may be conflicting views as to the wisdom of using medicine as an approach to evangelisation, there can be no doubt that in the world-wide activities briefly outlined here the Salvation Army is rendering social service of a high order. Pioneer work such as this, carried on in places in which there is no question of overlapping must command admiration and sympathy.

ELECTROCUTION OF MOSQUITO LARVÆ.

Dr. José F. Montellano, of the Argentine National Department of Hygiene, has had, says the *Semana Médica* (Buenos Aires), the happy thought of employing electric currents in the destruction of the larvæ and nymphæ of anopheles and other transmitting species in infected zones. Dr. Montellano has demonstrated by his experiments that the larvæ possess but a feeble resisting power to electric currents whether continuous or alternating. An official trial took place recently in Dr. Wernicke's department of the Bacteriological Institute, in the presence of the electrical engineer (Señor Luis J. Sidler) to the Anglo-Argentine Electric Company. Señor Sidler was impressed by the results obtained and promised, on behalf of the company, the necessary technical assistance for experimentation in the open. It is hoped that the new method will prove efficacious in the campaign against paludism. Dr. Araoz Alfaro, President of the National Department of Hygiene, has the matter under consideration with a view to a grant of the necessary funds for a trial of the method in the neighbourhood of Buenos Aires, and should the results be satisfactory, for the organisation of a large-scale campaign in the paludic zone in the centre and north of the Republic.

THEORIES OF PLACENTAL CIRCULATION.

THE subject of the placental circulation, with some aspects of which Prof. J. E. Frazer dealt in the Harveian Lecture before the Harveian Society on March 20th, forms an interesting chapter in the history of anatomical medicine. From the time of Galen it was held that the umbilical vessels of the fœtus were directly continuous with corresponding vessels in the mother, artery with artery and vein with vein. An almost necessary corollary of this belief—partly resulting from it, and partly, no doubt, leading to it—was the idea that the fœtal heart did not act. It is a curious thing that such a false opinion was held throughout the time when Aristotle, who had described the beating heart of the chick in the egg, was held in such high esteem, but it may be explained, perhaps, by this very fact, inasmuch as the chicken being a creature which, in the nature of things, cannot link up with the maternal vessels, is therefore not in the same category as man and his nearer allies. Whatever may be the reason, the theory itself was, as Prof. Frazer showed, of great importance in affording ground for the Galenical explanation of the fœtal

circulatory structures. This explanation was upset, of course, by the Harveian teaching, and Harvey expressly denied the anastomosis between maternal and fœtal vessels. But he was not by any means the first to do this. Arantius probably holds pride of place in this respect, for, in his excellent account of the anatomy of the placenta, he describes the two circulations as separate, and denies any anastomosis at all between them. He was followed by many others, but his opinions were not upheld by Fabricius, Maitrejan, and Perpessac. Heister also seems to have been a disciple of the old school in this respect, and it is curious to find even Cheselden, as late as 1795, affirming his belief in the maternal blood supplying the fœtus. We note with satisfaction that, speaking generally, the leading men in this country were at one in following Hunter, whose own observations caused him to support Harvey.

A NEW ALCOHOL METHOD FOR PREPARING INSULIN.

IN a recent paper[1] by Dr. H. W. Dudley and Mr. W. W. Starling are recorded experiments on variations of the Collip process for the preparation of insulin. As pointed out by the authors, Collip's method consisted in the extraction of pancreas with plain alcohol; Doisy, Somogyi, and Shaffer improved the yield by the addition of acid to the extracting alcohol, whilst the present authors modified the method by using alkaline alcohol. They were led to this by the observation that insulin is readily adsorbed to a substance in a neutral or slightly acid medium, but not to anything like the same extent in an alkaline medium. They hoped that an alkaline solution would wash out the insulin more thoroughly. In spite of the fact that an alkaline solution favours tryptic action, it was found that their hopes were realised, and that a considerable improvement in the yield resulted. From a series of 43 experiments the optimum concentration of bicarbonate in the alcohol was found to be 85 g. per kilo of pancreas. The average yield of the whole series was 257 rabbit units, whilst that of the last eight, when the conditions had been standardised, was 412 per kilo. In one experiment 508 units were obtained. These yields are very much above those obtained by the plain or acid alcohol process. The paper represents a very large amount of valuable work. It was evidently in the press before the publication by Dr. E. C. Dodds and Mr. F. Dickens of the acetone-picrate process whereby methods of any kind involving the use of alcohol are likely to be superseded, and even higher yields obtained than those here recorded. The paper includes an important modification of Dr. Dudley's method of purification of insulin which will, in any case, be of substantial value.

THE HEALTH OF THE INDIAN CHILD.

THAT a systematic effort is being made to study and combat disease among children in India is shown by the special children's number of the *Deccan Medical Journal* (vol. ii., No. 1, January, 1924), edited by Mr. Hyderali Khan, F.R.C.S. Edin., who a few years ago was resident medical officer of a London children's hospital. This volume contains a number of articles, written by members of the Hyderabad Medical Association, describing the symptoms and treatment of the more prevalent children's ailments. These are not, as might perhaps be expected, ailments peculiar to tropical climates; they are the same ailments as occupy the attention of a London children's hospital, although their relative frequency presents striking differences. Rickets is mentioned only to emphasise its rarity, while infantile diarrhœa and tuberculous peritonitis, the two diseases in which we have noticed the most striking diminution in England during the last decade, appear to be extremely prevalent and even to be increasing. Dr. A. L. Sayeed, in his article on infantile diarrhœa, states that this ailment is commonly secondary to broncho-pneumonia, which would appear to be a reversal of the usual sequence in this country; he attributes the infection to swallowed sputum. Perhaps the most significant statements concerning the spread of children's diseases are found in the article on surgical diseases, by Mr. R. N. Coorlawala, F.R.C.S. Eng., superintendent of the Afzulgunj Hospital, relative to the serious increase in the incidence of surgical tuberculosis in the last 14 years. Of a total of 13,780 children treated in hospital during one year, over 8000 required surgical treatment, and the majority of these were tuberculous. The writer states that the increase has taken place among all classes of the community, and attributes it to such causes as the introduction of tuberculous cattle and to the large amount of dust due to vehicular traffic; he believes that over 50 per cent. of the abdominal cases are of the bovine type of infection, but gives no figures for the gland and joint lesions which formed the majority of his cases. He has, on the other hand, observed abdominal tuberculosis, even of the ascitic type, in breast-fed infants. Therapeutics receive their share of attention in this volume, and the description by Dr. Namasiwayam of an effective specific for pertussis —*Pongamia glabra*—which grows wild in the Indian forests, may well excite the envy of English physicians. The seeker after novelty will find it in the review of a recent work on infantile cirrhosis of the liver, a disease now becoming prevalent, which is "confined usually to the first male child of rich Hindus." The human side of the treatment of the child has not escaped the notice of the writers, and their efforts to combat the prejudice and superstition of mothers and "ayahs" are described with shrewdness and humour. The volume should be of real value to Indian practitioners.

THE INFLUENCE OF THE FACTORY SURGEON IN INDUSTRIAL WELFARE.

WE have recently indicated in a series of special articles the probable trend of future development in factory hygiene and some of the more pressing requirements of the moment. In a letter which appeared in our issue of March 1st Prof. E. L. Collis argued that, although industry needs a medical service, the post of certifying factory surgeon has existed for 80 years, but has failed to develop with the development of knowledge. It looks as though a new opportunity is now to be afforded to the surgeon. On March 22nd it was announced that the Home Secretary had appointed a committee to inquire into the working of the provisions of the Factory and Workshop Acts for the medical examination of young persons as to their fitness for employment in factories, and to consider the following points:—

(*a*) Whether the existing requirement of a certificate of fitness limited to a particular factory should be modified; whether any other changes should be made in the examination and certificate; and what arrangements should be adopted for the future.

(*b*) What measures should be taken for linking up the examination of young persons under the Factory and Workshop Acts with their examination under the school medical inspection service, and, if considered desirable, with other public health services of the country.

(*c*) What arrangements could best be made for providing medical supervision of young persons (where such supervision is considered necessary by the department) during employment in factories or processes where the conditions of work are unfavourable to health or physique.

The insufficiency of the services at present rendered is acknowledged by the certifying surgeons themselves, and their Association, in a report which is abstracted on p. 668, calls for extended activities. The Association holds that obligation lies upon the Government to establish "a sufficient and properly organised factory medical service," and it has in contemplation a definite scheme of procedure designed ultimately to promote this end. The most important points raised are the mechanism whereby the extended medical supervision and the

[1] Improvements in the Preparation of Insulin: Alkaline Extraction of the Pancreas. By H. W. Dudley and W. W. Starling. Biochemical Journal, 1924, xviii., 147.

raised standards of examination for young people, admittedly desirable, are meanwhile to be provided for. The advantage both to employers and the certifying surgeons to be gained by an extension of the duties of the latter is undoubted, and association of these surgeons with voluntary efforts such as welfare schemes should certainly be encouraged. In order to give some guidance to employers and surgeons on the remuneration that may fairly be demanded for additional work, a scale corresponding to that paid by infant welfare centres (a guinea per hour's work) is suggested as a minimum, and the recommendation is made that charges should be always per week, month, or year, never per visit paid. It is not likely that in the present state of national finance a comprehensive scheme of industrial medicine will be introduced by any Government. The suggestions made by the Association are likely to be useful in the interim, and indeed might well form the basis on which an Industrial Medical Service could be founded. Of especial value would be the closer association of doctors with the welfare workers, and the advice given to the latter on medical matters connected with their duties might with advantage include some talks on psychology. The factory hand who, when asked what troublesome factor in his conditions of work he would most like removed, replied "the welfare worker," voiced the legitimate resentment of many of his kind at tactless interference. With the help of the factory surgeon, the efforts on the part of the welfare worker to increase the comfort as well as the efficiency of the employee might be guided into directions which would be appreciated not only in increased output, but in greater content.

THE COMPOSITION OF BAYER "205."

SINCE its introduction Bayer "205" has always been surrounded by an air of mystery amounting almost to romance. Its powers as a trypanocide were at first said to be miraculous, whilst its toxicity was, according to all accounts, incredibly small. Its composition and formula were rigidly guarded, but the authorities of the Farbenfabrik Bayer stated that the substance contained neither arsenic nor antimony. The material was supplied only on the distinct understanding that it was for clinical use, and the person to whom it was entrusted had to give his word that no attempt would be made to determine its constitution. The clinical value of "205" cannot be doubted, since many eminent authorities, including P. H. Manson-Bahr[1] and F. K. Kleine,[2] have published series of cases treated with the remedy. A full review and bibliography of the clinical side of Bayer "205" is given in a recent article in the *Annales de l'Institut Pasteur*.[3] It would appear that the much vaunted low toxicity is apparent rather than real. For instance, in practically all of the recorded cases there has been albuminuria, which is quite a rare symptom following salvarsan treatment. In many cases 1 g. of Bayer "205" is followed by albuminuria, whereas 0·9 g. of salvarsan (N.A.B.) can be given at weekly intervals without any such sign. The ratio of the curative to the lethal dose may be very small, but the ratio to the dose causing toxic symptoms appears to be fairly high. The medical, and at the same time the national, value of "205" can hardly be over-rated. German workers have gone so far as to suggest that in "205" lies the key to Africa. It is thus not remarkable that for French and English authorities to obtain this substance was a very difficult matter, and it became obvious that independent research into the constitution, if successful, would be of the greatest possible value. Fourneau, Tréfouel, and Valleé started work with this object in view, and in the article referred to have put forward the formula of a substance which they state to be identical with the German Bayer "205" They were hampered at the outset by the difficulty of obtaining even a small quantity of the German substance. They were able, however, to overcome the rigid conditions laid down by the Bayer Company, and by "une voie très detournée," they obtained a few centigrammes. Indications of the lines upon which to work were obtained by studying a series of patents taken out by the Bayer Company on complex urea-like substances, obtained by coupling the amides of amino naphthalene sulphonic acids. Starting with these compounds and armed with a knowledge of the work done on salvarsan, these investigators set out on what appeared to be an almost hopeless task. Chemically it is possible to have an infinite number of compounds, and, at the same time, it is all but impossible to be sure of the exact manner in which the acids are coupled in any given substance. The investigators must have been imbued with wonderful hope and keenness. As they say, "Bien des fois même, découragés, nous avons eu le désir d'interrompre la poursuite d'un but qui semblait fuir devant nous." Their courage and patience seem to have been rewarded, since in their compound "309" they appear to have produced a substance identical with Bayer "205" They reproduce the formula and state that its chemo-therapeutic ratio—i.e., ratio of curative to toxic dose—is equal to that of the original German compound. Owing to the small quantity of "205" at the authors' disposal, it was impossible to prove beyond doubt that the two compounds were the same, but in all the reactions that they were able to try both substances behaved in an identical manner. The therapeutic tests were carried out on mice, and the final clinical test has yet to be performed. The authors are making trials of "309" in Africa, and it is hoped that good results will be obtained. If these are satisfactory, as one is justified in hoping, the discovery of "309" will form a landmark in chemo-therapeutics; but whatever the outcome of the clinical tests may be, the zeal and patience of the authors deserve the utmost commendation.

A NEW TREATMENT FOR HYPEREMESIS GRAVIDARUM.

AMONG the various morbid manifestations which may happen to a pregnant woman that of vomiting, which may become uncontrollable and constitute a danger to life, is undoubtedly the most important, and its treatment has for a long time been a problem among obstetricians. It is unnecessary here to enumerate the various therapeutic and operative measures which have been employed to combat this disease, but we may call attention to a new method which Dr. Pietro Castagna [1] has recently put forward. He claims to have obtained excellent results from the intravenous injection of a concentrated solution, 35 per cent., of chloride of calcium given in doses of 2 c.cm., a cure having resulted after the third or second or even after the first injection. His technique in order to avoid injury to the perivascular tissue is as follows. Before inserting the needle into the vein in the elbow, care is taken by aspiration that it does not contain any trace of the fluid, and the injection having been made a little blood is aspirated several times and re-injected into the vein so that the walls of the needle are well washed out, as to ensure that after it is withdrawn from the vein not the least trace of the caustic fluid is left in its track. By this method any sloughing action upon the paravascular tissues can be avoided, the slight erythema produced being easily remedied by wet applications. Details of five cases are given, four of which were primiparæ and in whom the vomiting was of an uncontrollable character. Treatment by morphine, adrenalin, orexin, oxalate of cerium had failed to relieve the violence of the vomiting, so that in one case rectal feeding had to be resorted to. All the cases responded promptly to the injections of chloride of calcium and the pregnancies went on to full term. These reports seem encouraging enough to

[1] Il Policlinico, Practical Section, xxxi., Feb. 25th, 1924.

justify a further trial of this method of treatment before having recourse to artificial interruption of pregnancy in the more severe cases.

PLANTS AND MEN.

ALTHOUGH Sir Frederick Keeble made no direct mention of medicine in his delightful address last week at the Royal Institution on the Plant Commonwealth and Its Government, yet there was much in what he said which appealed particularly to the trained medical mind. The lecture was largely concerned with the transmission of messages in plants. Sir Frederick Keeble depicted the vegetable organism as being constantly assailed by impulses to which it reacts. He showed how the plant cell is more constantly subjected to stimulus than are the cells of our own body and how mistakenly we employ the term to lead a "vegetable existence." Moreover, the sensitiveness of the plant is so acute that it can react to the stimulus of a weight so minute that it would be imperceptible to the most sensitive human skin. The transmission of impulses is carried out in the lecturer's opinion by hormones. The plant commonwealth is Victorian—it has but one means of transmission, the old post office—as opposed to the neo-Georgian animal mechanism, with its telephones and wireless, its nerves and arteries, veins and lymphatics. Experiments in which the growing tip of a leaf or of a root is removed and then stuck on again with a layer of gelatine through which hormones can pass were related to prove the route by which plants transmit messages in their commonwealth. The activity of plant cells in response to trauma, and the damage done to the wounded surface by over-washing were illustrated by diagrams, and were of extraordinary interest to the medical man when compared with the latest teaching of aseptic and antiseptic surgery. There can be no doubt that advances in human physiology and therapeutics might well follow on experiments devised on the lines described by Sir Frederick Keeble.

THE L.C.C. SCHOOL MEDICAL STAFF.

LAST week the London County Council came to a decision which will result in a reorganisation of its medical department. Following the example of the Ministry of Health, a new grade of officer has been created, designated "senior medical officer," with stipend appropriate to the position. By effecting certain economies, the cost of the department under the new scheme will be less than formerly, with the result that it has been possible to increase the salaries of the assistant medical officers. Perhaps the most interesting part of the scheme is the declaration that in the future greater use will be made of part-time officers than has heretofore been the case. Diverse views are still held as to the advisability of the public medical services being composed entirely of whole-time officers or largely of part-time officers, and it is noteworthy that the London County Council should after considerable experience of either course resolve that "as large a proportion as possible, compatible with efficiency, of the subordinate medical staff should be engaged on a part-time basis." Apart from the senior officers there are at present 30 full-time permanent assistant medical officers in the department, and these posts will be reduced to 23 as and when opportunity arises. Eight assistant medical officers, who are engaged on a yearly basis, are to be replaced by part-time officers. This is the extent of the contemplated change in the immediate future.

NOBLESSE OBLIGE.

WE understand that Lord Banbury has in the House of Lords, as previously on two occasions in the House of Commons, stated that he had the authority of THE LANCET for an assertion that dogs were not necessary for experiment. Such a statement is untrue, and Lord Banbury has already been informed that it is misleading.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

LXIV.

THE TREATMENT OF CERVICAL ADENITIS.

A CONSIDERABLE amount of discussion has taken place in recent years concerning the nature of enlarged glands in the neck. Formerly, it was the custom to regard chronic cervical adenitis as practically synonymous with tuberculous adenitis, but there was no real evidence for this view. The assumption that the persistence of a chronic enlargement of a gland is due to the tubercle bacillus is valueless. Investigation of the glands, after removal, in cases clinically identical often fails to show any tuberculous lesion, whilst bacteriological examination of the glands often only shows the presence of a streptothrix, streptococci, or staphylococci, and these, in many cases, apparently of a low degree of virulence. Consequently, it is now increasingly realised that a large number of cases of chronic adenitis are, at any rate in their earlier stages, of a simple nature and dependent on some chronic irritative lesion. The subject of local irritation in respect to the development of tuberculous glands is an exceedingly important one, and it has, I think, been proved satisfactorily that in a large majority of cases the incidence of a tuberculous process in a glandular group has been preceded by injurious irritation in some part of the region drained by the lymphatics afferent to the group.

Causes other than Tuberculosis.

In the region of the neck there are so many sources of possible irritation that the most thorough investigation must be undertaken before any drastic treatment of the actual glandular enlargement is embarked on. The scalp must be examined for impetigo, seborrhœic eczema, pediculi, and other lesions. The possibility of oral sepsis must be investigated, and carious teeth, alveolar periostitis, unhealthy tonsils, or ulcerative lesions of the fauces, tongue, and floor of mouth looked for. The ears must be examined for any evidence of discharge, whether due to infections of the external auditory meatus or to chronic suppurative otitis media, whilst adenoids must be looked for in the nasopharynx. It is not easy to say by which route the infective process more commonly enters, but it is probable that in the majority of cases in children, unhealthy tonsils and adenoids and carious teeth are responsible. It is quite remarkable, at any rate in the south of England, how the number of cases of extensive cervical adenitis has diminished since the teeth and tonsils have been properly attended to, so that it is quite unusual to see patients with large masses of glands in the neck, though this was quite a common sight 20 years ago.

That the tonsil is a portal of entry has been, I think, satisfactorily proved, and recently published investigations by Dr. S. R. Gloyne and myself [1] over a series of 300 cases of unhealthy tonsils associated with cervical adenitis showed that the infecting organisms were mainly streptococci (hæmolytic and non-hæmolytic) and pneumococci, whilst the tubercle bacillus was only found in the tonsil in 5 per cent. of the cases. If, as is probable, tuberculosis is a late and superadded infection, the most important factor in the treatment of chronic glandular enlargement, with a view to the avoidance of extensive operative interference, is the complete elimination of all primary foci of infection. If this is effected it will be found that in a large number of cases the glands subside and eventually disappear. Complete resolution should not, however, be expected always to take place immediately, and occasionally a year or more may elapse before the glands finally disappear. In slow cases especially, though it applies to all, good fresh air, preferably in the country or at the seaside (the latter usually better for adults)

[1] THE LANCET, 1923, i., 1202.

combined with the maximum of sunlight together with the use of syrup of iodide of iron, are most useful adjuncts. It is doubtful whether any external applications such as iodine influence the course of resolution perceptibly. Although in a large number of cases the glands tend to disappear under the general treatment outlined above, there remains a residue of cases in which the enlargement of the glands persists.

Conservative Methods.

This group may be dealt with either conservatively or radically. The exponents of conservative methods pin their faith to a carefully thought-out régime of sunlight and country or seaside air, metabolism being raised by graduated exposure to the open air and by sea bathing. Should a gland break down it may be dealt with by aspiration with a sterile needle and the application of pressure or the injection of bismuth and iodoform emulsion. Merely emptying the gland will, in many cases, cause it to subside. If frequent aspiration is likely to be necessary the use of a seton is sometimes advocated. This method is more commonly adopted in France, but recently has had its advocates in this country. If this method is tried, a seton made of a double thread of strong silk, with the points of entrance and exit at some distance apart, is probably best and it may be left in for two to three weeks. At the end of this time suppuration has usually ceased and a cure is obtained with the formation of very small punctiform cicatrices which are hardly visible. As a rule, however, broken-down glands heal satisfactorily if opened by a small incision, their contents evacuated, and the abscess very gently scraped. It should be drained, not packed, by a small ribbon of bismuth gauze.

X rays have been found of great value in the healing of sinuses, often one or two applications being sufficient. X rays are also particularly useful in enlarged glands where a good deal of periadenitis is present. Injections of tuberculin in properly graduated doses, at suitable intervals, have in some instances proved a useful help. There is no doubt that under such treatment as the above large numbers of cases of cervical adenitis have become perfectly well. Many of these cases had been proved to be of a tuberculous nature, and the fact that they were cured tends to show how remarkable is the natural reparative power of the body against tuberculous infection.

Radical Methods.

The advocates of the more radical method of treatment do not deny that by many methods of treatment improvement, and possibly cure, may be brought about; but they are inclined to doubt whether such cures are permanent or the methods applicable to the more extensive cases the tuberculous nature of which has been definitely proved. They also maintain that the time of recovery would be shortened considerably by surgical treatment. In such cases more active surgical intervention is suggested as the alternative. Naturally, the extent of the operation must depend on the requirements of each particular case, but it should be the aim of the surgeon to get rid of the whole mass of infected glands as thoroughly and completely as possible. I have already mentioned that it is quite unusual to see many cases of very extensive cervical adenitis in the south of England, but they do undoubtedly occur in other parts of the country, and this fact must demand special and perhaps more radical methods of treatment. Incidentally, a clue may be afforded to the cause of the numerous cases of extensive disease occurring in a particular locality and the possibility of some form of preventive treatment being instituted. Some years ago an elaborate investigation by Dr. A. P. Mitchell [2] showed that cow's milk containing bovine tubercle bacilli was clearly the cause of 90 per cent. of the cases of tuberculous cervical glands in infants and children residing in Edinburgh and district. If such is still the case it is obvious that this source of infection could be dried up at once if the local authorities possessed and used proper powers for the control of the milk-supply, or if all milk was sterilised before use.

It must, however, not be assumed that this explanation holds universally, and the extent to which the milk of tuberculous cows is actually responsible for the infection of mankind with tuberculosis is very variable in various places. Statistics on similar lines to those just mentioned give the surprisingly low figure of 1 per cent. in Berlin, whilst in Italy the infection of human beings with tubercle bacilli of the bovine type is almost equally uncommon.

Advanced Cases of Proved Tuberculous Nature.

Be this as it may, the necessity of dealing with advanced cases of cervical adenitis of a tuberculous nature is still present. It is maintained by the advocates of helio-alpine treatment that progressive insolation in high alpine surroundings does produce remarkable cures even in advanced cases, and that large masses of indurated and adherent glands may be completely absorbed in six months, or where sinuses are present the whole infected gland may be extruded as a sequestrum, and the sinus rapidly heal with the formation of a supple scar. In this country, however, extensive surgical removal of the whole infected area provides the best chance of a satisfactory result. In the neck such procedure may involve the complete dissection of the infected glands in the anterior triangle, but may also demand the sacrifice of the sternomastoid and the elimination of all the posterior group of glands lying on the splenius and levator anguli scapulæ muscles. Excellent results have been obtained from such drastic procedures as these, and the necessity for them should not either be overlooked or dismissed.

Conclusion.

In conclusion one may say that (1) all primary foci of infection (tonsils, teeth, &c.) should be eliminated and adequate time allowed for the subsidence of the secondary adenitis; (2) if this fails to occur, conservative surgical methods combined with general and special therapeutic measures should be tried; (3) in the more extensive cases a thorough and complete removal of the whole of the infected glands should be effected.

WALTER G. HOWARTH, M.B. Camb., F.R.C.S. Eng.,
Surgeon to the Throat Department, St. Thomas's Hospital.

The Services.

ROYAL ARMY MEDICAL CORPS.

Capt. J. A. Charles, late R.A.M.C., Mila., to be Capt.

MILITIA.

Capt. D. M. Lyon to be Maj.

TERRITORIAL FORCE.

Maj. A. W. Howlett, from the half-pay list, is restd. to the estabt.

Maj. A. R. Moodie to be Lt.-Col. and to comd. 152nd (High.) Field Amb.

D. R. Owen to be Lt.

Sanitary Companies: Maj. (Bt. Lt.-Col.) R. E. Lauder is ret. on completion of tenure of comd. of the 7th Southern San. Co., and retains his rank.

D. W. E. Burridge (late Lt., 5th Bn., W. York R.) to be Lt.

TERRITORIAL ARMY RESERVE.

Lt.-Col. H. F. W. Boeddicker, from active list, to be Lt.-Col.

Capt. G. F. Hardy, from active list, to be Capt.

ROYAL AIR FORCE.

Flight Lt. (Hon. Squadron Leader) A. G. Lovett-Campbell relinquishes his temporary commission on account of ill-health.

INDIAN MEDICAL SERVICE.

The King has approved the admission of the following: To be Lieutenants: J. E. Gray, J. S. Riddle, G. P. F. Bowers, R. McRobert, G. Dockery, J. C. Drummond, F. H. Whyte.

The King has approved the relinquishment of his temporary commission by Capt. Nawab-ud-din, who is permitted to retain the rank of Capt., and the retirement of Lt.-Col. S. A. Harriss.

DRUG INCOMPATIBILITY.

A NOTE ON GENERAL PRINCIPLES FOR THE GUIDANCE OF PRACTITIONERS.

BY PERCY MAY, D.SC. LOND., F.I.C.

FROM time to time, most practitioners and physicians encounter cases of incompatibility of drugs with one another, or with the solvent or with the body fluids. In many cases these cannot be easily foreseen, and it is obvious that a detailed list of all recorded cases would be excessively lengthy—and, moreover, incomplete almost as soon as it were written. Certain general principles can, however, be pointed out as a help in avoiding pitfalls of this kind.

It is not proposed to deal here with cases of therapeutic incompatibility, but to confine our attention to chemical and physical incompatibilities. But in this connexion it should be noticed that an apparent chemical or physical incompatibility need not necessarily prevent the useful therapeutic action of the drugs. For example, the products formed by the double decomposition of two substances may be therapeutically equivalent to the original substances, and in this case the incompatibility is more apparent than real. Even if one of the products of double decomposition is insoluble it may be quite effective therapeutically, though in this case its formation is undesirable on account of the difficulty of ensuring accurate and uniform dosage in a mixture containing sediment. Instances of insoluble but therapeutically very active substances are numerous; it may be sufficient to mention calomel, which is one of the most insoluble salts known, and the purgative derivatives of anthraquinone, the therapeutic efficiency of which is roughly proportional to their insolubility. On the other hand, there are cases where the formation of insoluble substances may be very dangerous where these are of a toxic nature. In some cases this happens without the actual appearance of a sediment if another solvent be present in which the insoluble substance can dissolve and form a separate layer. A case of this type is quoted by Gilmour.[1]

Liq. morphinæ	1 oz.
Liq. atropinæ sulph.	20 minims.
Spt. ammon. aromat.	4 dr.
Spt. chlorof.	6 dr.
Aqua ad	6 oz.

In this case the salts cause separation of some of the chloroform as a bottom layer, and the spt. ammon. aromat. sets free the alkaloids from their salts. As the free alkaloids are far more soluble in chloroform than in water, they are extracted by the former, and are therefore concentrated in the bottom chloroform layer. Unless the bottle is well shaken before each dose, there is a possibility of the last dose containing a fatal quantity of alkaloids.

Incompatibilities of Drugs.

Taking first the most important group of incompatibilities, those of drugs with one another, we find first the simple cases which should be obvious to all possessing a rudimentary chemical knowledge. These include acids with alkalis, calcium salts with alkaline carbonates and phosphates, silver salts with chlorides, &c. Other similar cases, where two soluble salts react to give a precipitate, are well known, and need not be detailed. Their occurrence is readily manifested, and the cause can quickly be detected. As mentioned before, the formation of a precipitate does not necessarily affect the therapeutic efficiency of the mixture, but is usually undesirable on account of the difficulty of accurate dosage. Similarly, the incompatibility of an acid and an alkali need not in all cases be of significance, as long as the salts formed have the desired therapeutic effect, although in this case it would be better to prescribe the salt in the first instance.

Other cases of slightly less obvious incompatibility are those in which we have to deal with substances which, although not usually regarded as acids or alkalis, nevertheless react as such. Amongst compounds of acid reaction should be included salts of strong acids with weak bases, including most of the soluble inorganic salts of iron and the heavy metals, and a large number of the soluble salts of the alkaloids with strong mineral acids—i.e., hydrochlorides, sulphates, and nitrates. A substance of which the strongly acid nature is often unrecognised is saccharin. It is one of the strongest organic acids, and this fact should be recognised in prescribing it. In cases where its acidity may be undesirable, its stable and soluble sodium or ammonium salt (soluble saccharin) may advantageously be used instead. There are also some substances which are neutral when quite pure, but which readily give acid decomposition products when in solution or in presence of moisture. Spirits of nitrous ether and liq. ethyl nitritis are good examples of this type, and for this reason it may be advisable to neutralise the spirit with potassium bicarbonate before using it in mixtures where the presence of acid may be a disturbing factor.

Amongst the substances which it is inadvisable to prescribe with compounds of acid reaction are ammonium acetate, tartar emetic, all nitrites, the soluble salts of salicylic and benzoic acids, &c. The alkaline nature of the sodium and potassium salts of weak acids, such as the carbonates, is well recognised, but it should be noticed that borax is also strongly alkaline, and on this account is incompatible with many substances. Thus, for example, solutions of borax are sufficiently alkaline to absorb carbon dioxide with formation of sodium bicarbonate and boric acid, and when warm their alkalinity is even great enough to decompose chloral with formation of chloroform and sodium formate. Solutions of borax also precipitate alkaloids from solutions of their salts. Borax precipitates insoluble borates of nearly all the metals from solutions of their salts, though these precipitates are sometimes soluble in excess of borax or in solutions of ammonium salts. The presence of glycerine often prevents this precipitation. Borax and hydrogen peroxide, though not actually incompatible, should be prescribed together with caution, as hydrogen peroxide is unstable in alkaline solution, and the pressure of oxygen evolved from it may burst the container. On the other hand, the alkalinity of borax accounts for many of its valuable properties, such as its power of dissolving casein, fibrin, uric acid, and many resins, and of forming stable emulsions with many oils, often superior to those obtained with lime. One striking peculiarity of borax is the fact that it develops an acid reaction in the presence of glycerine, and is then incompatible with carbonates, from which it liberates carbon dioxide. Glucose, honey, and other polyhydroxy-alcohols share this peculiarity with glycerine. Another incompatibility of borax is that it forms a moist mass when triturated with alum, through liberation of the water of crystallisation of the latter. Sodium or potassium compounds of weak acids are sometimes strongly alkaline, and veronal-sodium, for example, is sufficiently alkaline to cause evolution of ammonia when prescribed with ammonium bromide. Potassium bromide should, of course, be used instead in this case. Soaps, also, have an alkaline reaction, and this should be remembered in connexion with soap emulsions and liniments. Many substances which are neutral when pure may be alkaline in the ordinary specimens met with in practice. For example, ordinary commercial sodium cacodylate is usually alkaline though it is neutral when quite pure.

[1] Pharm. Journal, 1916, xliv., 43.

Oxidising and Reducing Agents.

Another type of chemical incompatibility which may be foreseen by the application of chemical knowledge is that of oxidising with reducing agents. Some cases may be fairly obvious, but others are not so readily apparent. Amongst the oxidising agents used medicinally should be mentioned free iodine and preparations thereof; hypochlorites (including bleaching powder); organic chloramines, such as chloramine-T and halazone; permanganates; ferric salts (particularly the chloride); hydrogen peroxide; nitrites in the presence of acid, and notably preparations containing ethyl nitrite and amyl nitrite; nitric acid; potassium chlorate, &c. Reducing agents are not so frequently used as oxidising agents, but many substances can act as reducing agents in presence of a strong oxidising agent. For example, phenol (carbolic acid) readily reduces permanganate of potash, as do many other organic substances, and it is therefore useless to attempt to utilise the bactericidal properties of permanganate in conjunction with those of phenol. Alcohol and many other organic compounds frequently reduce strong oxidising agents. More definite reducing agents frequently used are sulphur dioxide, sulphites, hydrosulphites, and sulphides, ferrous salts, iodides in acid solution, most free metals, and notably mercury and nearly all finely divided or colloidal metals, formalin, paraldehyde, hexamine, and many other organic compounds. It stands to reason that an oxidising agent will be incompatible with a reducing agent, and these lists will indicate various pairs of incompatibles which might be encountered in practice. But a more remarkable incompatibility sometimes met with is that of two oxidising agents together which reduce each other with liberation of free oxygen. Hydrogen peroxide and permanganate are a pair of this type, and are reduced to water and manganese dioxide with evolution of oxygen, and therefore should not be prescribed together. Chloramine-T is another antiseptic oxidising agent to which this applies, as it reduces hydrogen peroxide with evolution of oxygen. Hydrogen peroxide is also reduced by alcohol, and is reduced catalytically by many substances, amongst which organic silver compounds are noteworthy.

Some Special Cases of Chemical Incompatibility.

We must now consider a few cases of special chemical incompatibility which cannot be referred to a general type and therefore cannot be so readily foreseen. One of these, which has been previously indicated, is that of chloral hydrate which is incompatible with alkali such as spt. ammon. aromat. with formation of chloroform and sodium formate. Hexamine is noteworthy among the substances which have many incompatibilities, and caution should always be used in prescribing it with other substances. Substances which can be converted by simple chemical changes into more toxic substances should, of course, be prescribed with great care, and should usually be given by themselves, and not in conjunction with other drugs. Calomel is one of these, as it is rather easily oxidised to corrosive sublimate. Bromides and iodides are dangerous with calomel, particularly in presence of oxidising agents, and free iodine or its preparations should be most carefully avoided when calomel is being administered. Another frequently quoted case of danger from calomel is its incompatibility with antipyrine. This is said to give a very toxic mixture, and it has been suggested that corrosive sublimate is formed according to the equation[2]:—

$$6\,HgCl + 2\,C_{11}H_{12}O_2N_2 + H_2O = 2\,Hg + Hg_2O + 2\,HgCl_2 + 2\,C_{11}H_{12}O_2N_2,\,HCl.$$

But this is doubtful, and it has been suggested that the formation of corrosive sublimate from calomel under the conditions of therapeutic practice is a myth. On the other hand, there can be no doubt of the need of the greatest caution in the use of calomel with organic compounds, as many of the organic mercury derivatives are most intensely toxic and far more dangerous than corrosive sublimate, so that the formation of only a trace of them would be attended with the gravest risk. This seems the more likely explanation of the poisonous incompatibility of antipyrine and calomel, and according to Paderi[3] a compound, $HgCl–N(CH_3)(OH)–C_{10}H_9ON$, is formed, which is more toxic than corrosive sublimate.

Antipyrine is also incompatible with nitrous acid or with sweet spirits of nitre, unless the latter is previously neutralised, as free nitrous acid converts it into nitroso-antipyrine. Tannic acid or tannin is another substance of many incompatibilities. It is precipitated by ferric salts, silver salts, and many other metallic salts, by acids, and by gelatin. An example of a complex change in which more than two substances take place is furnished by galenical preparations of quinine and cinchonine which in presence of organic acids and ferric salts sometimes darken with the formation of quintoxin and cinchotoxin, both of them extremely toxic substances, especially the latter.

Another interaction of ferric salts with organic acids which is of interest is the oxidation of citric and other acids with evolution of carbon dioxide. This only takes place in daylight, and is a purely photochemical change. We have here, therefore, a physico-chemical incompatibility, and this forms a connecting link with the following section, which deals with cases of a physical rather than a chemical nature.

Physical Incompatibility.

The chief physical cause of incompatibility is the influence of one dissolved substance in lowering the solubility of another, whereby the latter is thrown out of solution. When one of the substances is of a saline nature, this phenomenon is often known as "salting out." This happens most readily when two substances are present having a common ion, as in the well-known method of purifying sodium chloride by passing hydrogen chloride into its saturated solution. In this way codeine bromide is salted out by an excess of sodium bromide, and very many other instances of this type are to be met with. As most salts are less soluble in dilute alcohol than in water, the presence of alcohol in any form is liable to cause crystallisation of sparingly soluble salts. Potassium chlorate, for example, crystallises out very readily in the presence of alcohol. Conversely, substances like chloroform which are more soluble in pure water than in salt solutions are thrown out of solution by saline substances, and there is sometimes a risk of chloroform being thrown out as a separate layer from prescriptions made up with chloroform water.

In powder mixtures trouble may be caused by another common physical property—namely, the mutual lowering of the melting-point (m. pt.) of the components of a mixture. It is well known that an impure substance has a lower melting-point than when in a pure state, and therefore it is not very surprising to find that where two substances of moderately low m. pt. are mixed, the m. pt. of the mixture may be low enough for it to be liquid at ordinary temperatures. For example, salol (m. pt. 43° C.) gives with antipyrine (m. pt. 114° C.) a mixture of m. pt. 30° C., with menthol one melting at 28° with chloral hydrate, one melting at 17° C. with camphor (m. pt. 175°), one melting at 6° C., and with guaiacol one melting at 3° C. The first two of these may liquefy in hot weather, and the others will be liquid at all ordinary temperatures. Sometimes a combination of three substances is necessary to produce this effect to an appreciable extent, a pasty mass being formed, for example, from antipyrine, phenacetin, and acetanilide when mixed together. Many other examples of this kind can be found. Another physical phenomenon which may cause solid mixtures to become fluid or pasty is the withdrawal of water of crystallisation from one substance, by another which dissolves in the water thus abstracted. Tartaric acid in this way forms a tasty mass with Glauber's salt or with borax. Many other examples of this type may be found when a substance very soluble in water is mixed with one containing water of crystallisation.

[2] Weidenkoff: Pharm. Zeit., 1910, lv., 780.

[3] Journal of Chem. Soc., 1920, cxviii., i., 94.

Incompatibility with the Body Fluids.

Having now dealt at some length with cases of incompatibility of drugs with one another, we will glance at a few cases where some part is played by the body fluids. The most important point in this connexion is the strong acidity of the gastric contents—namely, about pH 1·77 or about N/60 HCl. The alkalinity of the small intestine is of a lower order, and in this case the hydrolytic action of the pancreatic enzymes is of perhaps greater importance than the actual alkalinity. The two in conjunction hydrolyse, for example, acetyl salicylic acid into sodium acetate and sodium salicylate, and it will then react as a mixture of these. A case of possible incompatibility with the gastric contents is afforded by antipyrine and hexamine, which, under these conditions of acidity, form an insoluble crystalline compound.

Many interesting cases have been recorded of undesirable effects being produced by one drug reacting through the body fluids with another drug taken previously or by a drug taken internally reacting with another taken externally. For example, mercury oxycyanide is a non-irritant and valuable medium for bladder and urethra irrigation, but in patients under the influence of iodides it causes intense cystitis through formation of irritant mercuric iodide. A case has been observed[4] of severe burning of the skin on the application of hydrogen peroxide lotion to a patient undergoing internal treatment with potassium iodide through the liberation of free iodine. In the same way colourless tincture of iodine taken internally has caused great irritation of the skin on application of a mercurial ointment through the formation of irritant mercuric iodide. On account of the irritant nature of mercuric iodide, dressings of corrosive sublimate should not be used on wounds previously treated with tincture of iodine. If this should happen, the mercuric iodide is best removed by washing with potassium iodide solution. A similar incompatibility is recorded in the use of external applications of mercury and the internal use of sulphur compounds, brown or black stains of mercuric sulphide having been produced on the skin.

Incompatibility with a Solvent.

With regard to incompatibility with a solvent, the tendency of alcohol and other organic solvents to precipitate salts from aqueous solutions has already been indicated. Of course, all prescriptions should be made up with distilled water, but when the dilution of a mixture or the solution of a tablet or powder is left to the patient, tap water is generally used. In a few districts this is nearly pure, but most tap waters are hard, and so may often give untoward effects on account of the calcium and magnesium salts and sulphates which they contain. Most of these effects will be of a nature to be expected from such substances, and will include some slight precipitation of carbonates, phosphates, &c. The following is an interesting case of the effect of hard water recently noticed by us. Tablets of hexamine additive compounds, such as cystazol, readily disintegrate in soft or distilled water, but in hard water they only do so very slowly and with difficulty. By an apparent paradox, they disintegrate far more rapidly if allowed to soak in a small quantity of water to which the remainder can be subsequently added than if they are initially treated with the full quantity of water. The explanation is that in a small quantity of hard water there is not sufficient dissolved matter seriously to interfere with the disintegration of the tablet.

It is hoped that the foregoing review of the causes of incompatibility will be of some use in coördinating and classifying the large number of cases which are constantly being brought to notice.

[4] THE LANCET, 1912, i., 597.

THE Wellcome Historical Medical Museum will be closed from April 1st to the 30th inclusive for redecoration and cleaning.

REPORT OF THE ASSOCIATION OF CERTIFYING FACTORY SURGEONS

(1922–23).[1]

THIS report, which deals with a period of two years, opens with the remark that the Factory Acts are much in need of amendment and overhauling, and welcomes the announcement in the King's Speech of a consolidating Bill.

Reference is made to the considerable number of papers on industrial medical subjects read at the annual meeting of the British Medical Association in Glasgow (1922), and the holding of a conference of associations and bodies so interested, at the Royal Sanitary Institute, London, in June, 1923. This gathering was arranged by the League of Nations Union with the object of creating in the minds of those particularly concerned a more perfect understanding of the functions and activities of the International Labour Organisation, and a knowledge of how this body as a coördinating centre can materially assist external efforts by providing useful advice and information. Government factory and medical research departments, workers' unions, employers, welfare organisations, and medical associations made excellent response to an invitation to send representatives.

Work of the International Labour Organisation.

A valuable feature of the conference was a preliminary address by Mr. H. A. Grimshaw, one of the principals of the Diplomatic Section of the Central Office at Geneva, on the status and scope of the international organisation. Mr. Grimshaw referred to the common but erroneous belief that this institution is some sort of amalgamation of trade-unions, soviets, or brotherhoods, and pointed out its real position as a well-defined unit in the League of Nations constitution established by the Treaty of Versailles. He showed how its function is to secure by international action the adjustment of conditions of labour throughout the world to the requirements of justice and humanity, and that its constitution is by membership of subscribing States at present numbering 54. He explained how at periodical conferences, to which each member State sends four delegates, representing employers (one), employed (one), and the Government (two), draft conventions are formulated, recommendations with a view to coördinated legislation are drawn up, and scientific commissions of investigation are appointed. Also how a permanent staff at Geneva collects information from all quarters, both for conference needs and for the use of subscribing States, and that much of this would be available to recognised associations who cared to apply officially. He further stated that the fine library gathered together by the organisation would be at the service of duly accredited representatives of such associations visiting Geneva.

Four main industrial health questions were discussed: Safety and protection in industry; industrial fatigue; industrial disease and injurious processes; and the health of women workers. In all these discussions particular attention was directed to the influence which can now be brought to bear by the international organisation in coördinating the work of experts in various countries and in obtaining effective and uniform action among separate industrial communities. The various bodies represented certainly owe a debt of gratitude to the League of Nations Union for taking the initiative in bringing together this unique gathering of British experts.

The Position and Prospects of the Certifying Surgeon.

In addition to rendering an exceptionally useful account of the year's working, the annual report for

[1] Manchester, 1924.

1921 ventured to make a somewhat special feature of reviewing the position and prospects of the certifying surgeon. In dealing with this subject three points were specially emphasised. The first had relation to the obligations of the Government towards the establishment of a sufficient and properly organised factory medical service, and sought to demonstrate that, however desirable statutory reform might be from a health and efficiency point of view, there would be little likelihood of any definite official action being initiated whilst national finances are in so precarious a state. The second point dealt with the powerful move which is being made to influence industrial opinion on the advantages to be gained in health and efficiency from the voluntary establishment of welfare schemes and a sufficient measure of medical supervision over workers and work places. The third point dealt with the so-called works' doctor, the advisability of certifying surgeons getting into touch with the voluntary effort movement, and the mutual advantages to be gained by employer and surgeon if arrangements are made for the latter to take up, as far as possible, any extension of medical duties at factories within his own district. The Council had good reason to believe that the publication of the definite views of the Association on the subject of improved medical supervision and on its attitude towards an extension and a higher standard of examination for young people had met with the approval of contemporary bodies and associations interested in bringing about healthier conditions in industry.

At a conference organised by the Industrial Welfare Society to consider the "value of medical supervision in industry," which was held in Manchester on June 26th, 1922, the Association was represented by six members of the Council officially as well as by other certifying surgeons. The statutory position and duties of the certifying surgeon were explained by Dr. S. A. Henry, H.M. Medical Inspector; Dr. T. Watts, Dr. H. E. Watkins, and Dr. W. F. Dearden illustrated the advantages to be gained by employers making arrangements with certifying surgeons for extended services, and the particular advisability of doing this where welfare work was already in operation. Dr. A. Glen Park showed, from his own experience, what useful work can be accomplished by appointing the district certifying factory surgeon as medical officer to any continuation school established in connexion with a factory.

The willingness shown on previous occasions by the Welfare Workers' Institute to coöperate with the Association explained the interest taken by this body in the proposed increased scope of the surgeons' executive and advisory functions. The honorary secretary availed himself of an opportunity to discuss the new policy with Miss Voicey, who was then secretary of the Institute, and was assured that it would be heartily welcomed by her fellow-members. This lady, however, very properly pointed out that if welfare supervisors were to coöperate successfully in obtaining improved medical service it would be necessary to establish a clear understanding on the all-important item of cost to the employer. The honorary secretary of the Association (Dr. W. F. Dearden) agreed therefore to bring the financial aspect of the question to the notice of the council with a view of obtaining an authoritative opinion on the minimum rate of payment which would be acceptable to certifying surgeons generally. He further agreed to contribute an article to the monthly journal *Welfare Work*, explaining the additional duties which should be taken up, and how to arrive at a standard for remuneration. The council agreed that charges could be suitably based on the minimum fee recognised by the British Medical Association as suitable for work of a similar class—viz., one guinea per hour—and that a fair amount for an annual contract, based on one hour's attendance per working week, would be £50; time taken up in travelling to and from, when allowed for in existing contracts, to be a matter for additional consideration.

Proposed Extension of Existing Duties.

The article was published in the *Welfare Work* issue of November, 1922, and was made the subject of a leading article. Further, the correspondence columns of the two following numbers contained a series of letters which favourably criticised the scheme outlined. A copy of the journal containing the article was forwarded to each member of the Association. It may be explained briefly that extension of existing duties was advocated in the direction of (1) a more detailed examination of young persons, (2) extension of the examination of young persons between 16 and 18 years of age, (3) re-examination every 12 months up to 18 years of age, (4) supervision of ambulance and first-aid equipment, (5) advising welfare supervisors on medical matters arising in connexion with their duties. The basis of an annual contract recommended was £1 per hour for an estimated 50 visits per year. If one hour be allowed for each visit the annual amount would be £50, if two hours £100, and if half an hour £25 to £30. Particulars had been received of a number of contracts entered into on the lines recommended. The remuneration had mostly been based on one guinea per hour, but in some cases the basis was higher. The Council would, however, like to have more information as to actual arrangements, whatever the basis, than is at present available. This departure from old-established routine was likely to have considerable bearing on the future prospects of the certifying surgeon, and members were asked to communicate their experiences to the honorary secretary.

Agreements.

It was emphasised that in making agreements members should let it be well understood that the old method of contracting for statutory services is not being disturbed. The seven days' obligation respecting certificates of fitness cannot be lost sight of, and if there is an *annual* contract in existence it must remain as such. The new arrangement was only to be regarded as an extension of the old one. The duties were increased and the remuneration was necessarily greater, but the agreement should still be for the year and the accounts presented quarterly. It would also be found advisable to commence any extension of duties at the beginning of a quarter.

It must be understood that the annual amount arrived at on the basis outlined, though considered to be fair remuneration in average cases, was the lowest that could be accepted; also that in assessing this amount a year had been taken to represent 50 working weeks at a maximum and not likely to be less than 48. Special circumstances, such as the value of the existing contract or the amount of the minimum visiting fee obtaining in a particular district by arrangement with the occupiers, would have a definite bearing on any new arrangement. It should also be noted that, as statutory duties are involved, the extended contract should be arranged with "the occupier," or some responsible person acting on his behalf, and the details of new duties thoroughly explained. In all cases the surgeon should quote an annual sum for periodical visits (weekly or fortnightly) of a specified duration; he should never quote per visit if he can avoid it. How the amount is arrived at can be explained, but is no part of the contract.

Improved Type of Examination.

The improved type of examination contemplated in the scheme undoubtedly involved the introduction of the medical card. The setting out of the card should be as simple as possible, and, though not overburdened with spaces little likely to be used, the provision made should allow for essential details of every case. The sample card reproduced gave a fair impression of how the requirements might be met. As medical experts mostly regarded it as necessary to have all medical particulars respecting a worker on his medical card, and therefore ready to hand, the greater part of the space on the back should be ruled off to show dates between which the worker had been absent

through illness, or through injury inflicted at the factory, and the nature of such illness or injury. A smaller space could also be allowed at the back for special notes. The number of cases that could be conveniently examined in one hour must depend very largely on the amount of care taken with each case.

MEDICAL CARD. *Young Persons.*

Name.	Department.	Date of starting.	Date of birth.
Previous employments and duration.		Eyesight. R. L.	
Previous illness or injury.		Teeth (carious).	
Present disease, defect or deformity.		†Physique.	
		†Nutrition.

Date.	Re-examinations—results and recommendations.	Height.	Weight.

Date of Exam. Signature

* Strike out "Not" if suitable.
† Signs may be used—o = normal; – = under normal; + = over normal.

Experience showed that whilst eight examinations might be made when the cases are straightforward it was really much better to take six and avoid being hurried or exceeding the time limit. Heights and weights were to be taken by the welfare worker, not by the certifying surgeon.

An essential point was uniformity, and the most certain method of securing this was for certifying surgeons in the various manufacturing areas to meet and agree upon a policy suitable to the needs of the particular locality. The Council would be glad to hear of such meetings, and the results.

First-aid Arrangements.

It was noted that the annual circular letter of the Chief Inspector dealt with those parts of the new Compensation Act affecting certifying surgeons. A prominent feature was the insistence on a certain degree of first-aid equipment in all factories, and in making this provision it is curious how closely our legislature should cling to tradition. As the early Factory Acts did not provide for any inspectors to enforce the requirements, and as notification of industrial disease and poisoning, together with regulation of dangerous trade processes became law without any provision for medical supervision, so was this very essential equipment made compulsory without any effective means for securing its sufficiency or proper application. As the earlier vital defects were remedied in course of time, and as the Home Secretary appeared to have certain powers in this particular matter, it might eventually come about that first-aid and ambulance arrangements would be placed under some degree of supervision by the certifying surgeon.

THE Chelsea Hospital for Women, in connexion with the Fund being raised at the London Mansion House, has received for its nurses' home (now building) £105 from Sir John Mullens, and £50 from the Worshipful Company of Mercers.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Death of Sir Walter Buchanan.

THE death of Sir Walter James Buchanan, M.D. Dub., K.C.I.E., occurred at his residence in Dublin on March 23rd, after a few days' illness, at the age of 62. A native of Londonderry and educated first at Foyle College in that city, Buchanan had a distinguished career as a medical student in Trinity College, Dublin, graduating M.B., B.Ch. in 1887. In the same year he won the University Travelling Prize in Medicine and passed into the Indian Medical Service. After some time passed as house surgeon in Sir Patrick Dun's Hospital, and in the National Eye and Ear Infirmary, Dublin, he went to the East. He took part in the Hazara Expedition in 1888, and in the Lushai Expedition in 1890. He served in the Manipur Field Force in 1891 and was awarded a medal and clasp. In the following year he joined the civil branch of the Service. From 1899 to his retirement in 1919 he was editor of the *Indian Medical Gazette*, and from 1902 to 1919 he was Inspector-General of Prisons in Bengal. As a member of the Indian Prisons Commission he visited the United States, China, Japan, and many other countries. Since his retirement Sir Walter Buchanan has lived in Dublin, where he has given frequent lectures on his travels. He had a retiring disposition, plain exterior, and unassuming manner, but it was obvious to all who met him that he was a man of unusual character and ability. His unexpected death will cause regret both in Ireland and in India.

The Tax on Anæsthetics in the Free State.

Last week in the Free State Senate Dr. W. O'Sullivan moved, "That, in the opinion of the Seanad, ether, chloroform, and other drugs used in the relief of the sick should be free of taxation." He said that he would appeal to the Minister of Finance to do away with that tax in his next Budget. It was inflicting a terrible hardship on rich and poor alike. The tax was proposed as a protective tariff in England. He instanced two cases where the patients had died before the drugs ordered arrived from England. Senator Jameson suggested that a small central store of these necessary articles should be established by the Government. By that means the drugs could be got at the store by the people needing them on paying the necessary cost. The resolution was passed with the addendum that arrangements should be made to obviate delay in transmission.

Central Midwives Board of the Free State.

The first meeting of the recently elected Central Midwives Board for the Free State was held last week. Sir Andrew Horne was elected chairman and Senator O. St. J. Gogarty vice-chairman. Arising out of a letter from the Joint Nursing and Midwives Council for Northern Ireland, it was decided that no further applications for the enrolment under the Act of midwives who were trained prior to 1918 would be accepted by the Board, as six years have now elapsed since the passing of the Act. Such midwives will in future be required to pass the examination of the Board.

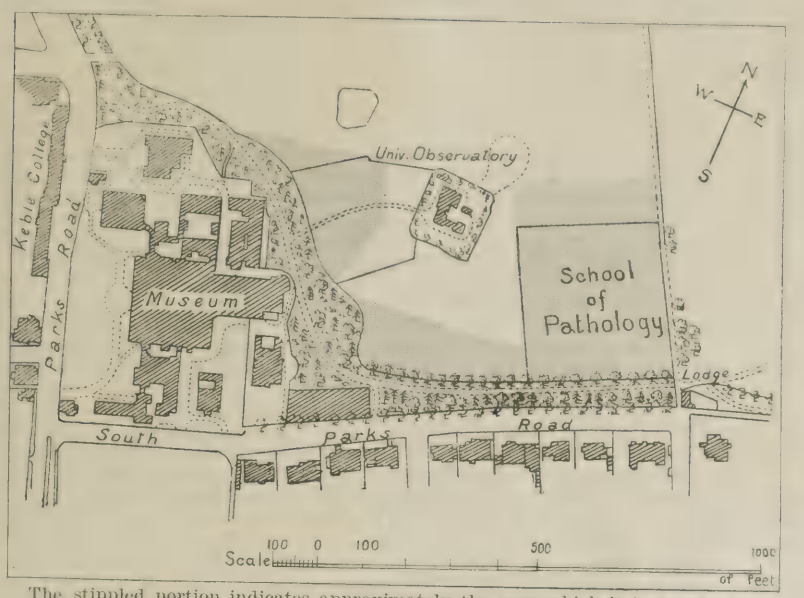
HORSHAM HOSPITAL.—This hospital, which moved into larger buildings, erected at a cost of £18,000, during the summer, is announced to be free of debt. It was noted at the annual meeting of governors held on March 19th that there was a balance on the year's working of £123 and a balance in the hands of the matron of £24. The contributory scheme had on Dec. 31st only been working for three months, but so satisfactorily has it been taken up that there are now 1750 contributors. The scheme brought in £196 in three months. The governors have been requested to consider the question of representation of the contributors on committees controlling the affairs of the hospital.

UNIVERSITY OF OXFORD:
EXTENSION OF SCIENCE DEPARTMENTS.

WE have received some particulars about the gift to Oxford University from the Rockefeller Foundation, and further details of the arrangements made by the University in connexion with it, and with the recent gift under the will of the late Sir William Dunn (pathology). A decree approved by Congregation on March 4th, and passed by Convocation on March 11th, proposed to set aside a certain area in the University Parks for the extension of science departments. A decree defining more precisely the space to be allocated to science departments was carried in Congregation on Feb. 20th, and subsequently in Convocation on March 4th. Had this decree been lost, an alternative decree was to have been brought forward at the same meeting; the opposition to the decree passed represented, for the most part, a preference for the alternative site, and not an opposition to the assignment of any site in the Parks. In the *Gazette*, in which notice of this decree first appeared, there was added a statement by the Hebdomadal Council, of which the following is a copy:—

"*Note 3.*—The Hebdomadal Council is of opinion that the settlement arrived at by the above decrees would provide for the developments of natural science during the present generation, but not for the establishment of the forestry department in the Parks or for the transference to the Parks of the present botanic garden and department."

The accompanying rough map shows the area now assigned to scientific departments, which is a little over 9 acres in extent, and is at least 2½ acres larger than the whole area at present covered by scientific buildings. By the assignment of space in the Parks the future development of the departments of natural science is assured for a long time to come, since it will now be possible to draw up a considered scheme, instead of having to fight on each occasion to secure the immediately adjoining bit of land for any new building, irrespective of its convenience in relation to the future of other departments.



The stippled portion indicates approximately the area which it is proposed to allocate in Decree 2 for extensions of the Scientific Department.

By the two magnificent gifts made recently to the University is secured not only a new department of biochemistry and a fully-equipped school of pathology with stables, paddock, &c., but also a new department of pharmacology in the quite modern pathology block—for which purpose the Dunn trustees have assigned £3000; also the whole space of the present department of biochemistry (part of the physiology building added in Prof. Gotch's time) becomes available for physiology, affording a very considerable addition.

It is suggested that the next requirements here (or among the next) are chairs and departments in hygiene and parasitology. The Regius Professorship of Medicine is only partially endowed.

BERLIN.
(FROM OUR OWN CORRESPONDENT.)

Further Developments in the Battle of the Clubs.

THE so-called strike of medical men over certain changes which had been brought about in club practice, as described in these columns (THE LANCET, Jan. 19th, p. 154), has been called off by the Leipziger Verband in the greater part of Germany. The strike has ceased on the condition that the status quo ante will be restored until further arrangements are made, which will, it is hoped, allow the maintenance of the free choice system. In Berlin, however, the battle continues, although the Berlin Medical Union, following the instructions of the Leipziger Verband, offered to work again under the former conditions. The Berlin clubs declined to accept that offer and even to be represented in the meetings called by the authorities to reconcile both parties. The clubs tried to appoint their own medical officers hoping in that way to get rid of the free choice system, but the local Insurance Office gave notice that if no agreement was reached they would appoint a commissioner to administrate the working of the clubs. The clubs appealed to the District Insurance Office, which cancelled the decision of the local Insurance Office. The district office went to the length of advertising in the Berlin and provincial daily papers, inviting medical men to apply for appointments as club medical officers. Although the district office has declared that this step was necessary, as it bears the responsibility under the present law for providing adequate medical service, this obvious partiality has caused great indignation in the profession. Medical men say that if the clubs had accepted the offer made by the Berlin Medical Union a sufficient number of doctors would have offered their services. The issue of the battle will depend entirely on the firmness of the Berlin doctors. The list of doctors in club practice includes, at present, not more than 60 names, whereas the total for Berlin should be at least 1350, at the minimum rate of one doctor per 1000 club members, according to the provision of the law. The great majority of names on the list represent medical men who are known to be of a low professional standard; and some may have been compelled by need to act against the interests of their professional brethren. These club doctors have formed a medical union of their own and invite, through the press, medical men in Berlin and elsewhere to join them. Two of their leaders have been excluded from the Berlin Medical Society for breach of medical ethics, this being in the history of that

society the first instance of cancellation of a member for such reasons. The outcome of the battle, which at present is the principal topic of conversation in Berlin medical circles, will have a far-reaching effect on the Berlin medical profession as far as it is connected with club practice. English readers may conclude from this somewhat detailed report how great the difficulties of the German profession are and how little help they are obtaining from the Government in their struggle. This is the more regrettable, as in Germany non-club practice for the majority of medical men is almost an impossibility.

Statistics of the Berlin University.

Although academical circles and representatives of the liberal professions, including medicine, have repeatedly issued public warnings as to the present handicaps of a professional career, the number of students in the Berlin university, and in other universities likewise, has not decreased to any great extent, being 12,581 this year as compared to 12,741 last winter. Of this year's figures, the men numbered 10,872 and the women 1709. The newly matriculated students included 2494 men and 428 women. It is, however, remarkable that compared with the students in other faculties those of the medical faculty and the dental students showed a rather considerable decrease. This year 1781 medical and 186 dental students were inscribed against 2088 medical and 274 dental students last winter. Apart from the Austrian students who enjoy the same rights and privileges as the German students, the number of foreign students has again increased, being 2650 against 1750 in the previous winter, although the fees for foreigners have been considerably raised. Among the foreigners the Bulgarians are the most numerous, with 191 men and 60 women. The great number of foreign women students is altogether very striking when compared with the figures for German women students.

Government Reward for Life-saving Abolished.

Until recently the Government paid a reward of 10 marks to any person who succeeded in restoring life in a case of serious injury, or of attempted suicide. A non-successful attempt was rewarded with 5 marks. In the latter case, of course, the reward was paid only if there had been reasonable hope from the outset that the injured person could be saved, as people were known to claim the reward for trying to revive persons who had been dead many hours or even corpses which had been taken from the water in a stage of decomposition. Owing to the depreciation of the currency the reward has not been claimed during the last years as the sum of 5 or 10 marks was totally worthless, and therefore by a recent Government order it has been abolished. The Minister of the Interior stated that when the currency was again stabilised the Government would have no funds to pay an adequate reward, and expressed the hope that the absence of pecuniary reward notwithstanding, nobody would refuse help where a life was in danger. A reward will continue to be given in exceptional cases, where the rescuer has been put to considerable financial expense and personal risk.

PRINCESS ALICE HOSPITAL, EASTBOURNE.—The fortieth annual report presented at the meeting of governors on March 21st foreshadowed a further enlargement in the near future, two houses in Bedfordwell-road having been purchased during the year for the sum of £6000. Beginning with 12 beds only the institution has now 80 beds, the latest addition being a new dispensary. During the year 913 patients were admitted as against 903 in 1922, and 373 major and 280 minor operations were performed. The finances are in a satisfactory condition, the deficit having been liquidated by Mr. Sydney Hudson, J.P. The amount received from patients and their friends towards the cost of maintenance amounted to £1319, and the governors expect that when it is more widely known that patients are expected to contribute according to their means towards the cost of their maintenance, the payments will steadily increase. Sir Charles O'Brien Harding announced that Mrs. Fosdick had given £100 for an extra X ray apparatus in memory of her husband.

Correspondence.

"Audi alteram partem."

PHYSIOLOGY AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR,—A well-known orthopædic surgeon recently asserted in my hearing, with apparent satisfaction, that as a student he knew little about the anatomy and physiology of the pons and medulla and that what he then knew he had since forgotten. And yet anatomy and physiology are the basis of scientific medicine. In physiology, at any rate, new facts of some importance are being discovered every month, although it may be years before they are brought to notice of clinicians even of the consultant class and in large towns. This state of matters is partly due to slackness on the part of the clinicians, but I think quite as much to the aloofness of the scientists, who are apt to underrate the knowledge and intelligence of the practitioner.

To remedy this deplorable delay in the spread of useful knowledge I would offer the following suggestions: (1) There should be a chemical, an anatomical, and—most needed of all—a physiological section of the Royal Society of Medicine; to which scientists should be encouraged to contribute abstracts of progress in their particular departments. (2) The medical journals read by clinicians should, like the *Journal of the American Medical Association*, publish week by week reviews of scientific progress by first-class men. If suggestion (1) were carried into effect it might only be necessary to report accurately the proceedings at the scientific sections.

I am, Sir, yours faithfully,

London, S.W., March 18th, 1924. THOMAS LUMSDEN.

*** We deal with this letter in a leading article. —ED. L.

CERTIFICATES OF INSANITY.

To the Editor of THE LANCET.

SIR,—A letter in the *Times* of March 17th, headed Certification of Lunacy, should, I think, not pass unnoticed. In it certain suggestions are made, the first being that "local boards of mental hygiene" should be set up consisting of two doctors, two barristers, and two county councillors. To this board all persons in "observation wards" are to have a right of appeal, either personally or by counsel, and by it the question of their sanity is to be determined. It may well be hoped that the process of certification and ordering reception may become, for the protection of the medical practitioner, a more definitely judicial function than it is at present, but it is obvious that such a board, inspiring, from the nature of its heterogeneous composition, but little confidence, would be unwieldy, slow in operation, and of an insufficiently magisterial character. Any of us acquainted with the rapid and decisive action that is often required can picture a board dealing either with the acute maniac, or the argumentative paranoiac, and can imagine the queer results that would emerge.

The second suggestion is that general hospitals and Poor-law infirmaries should be provided with "observation wards" to which all "alleged lunatics' private or pauper," should be sent in the first instance. That general hospitals would do well to provide accommodation for certain types of mental illness is, I suppose, generally admitted, but to send all "alleged lunatics" to "observation wards," whether in general hospitals or in infirmaries, for a preliminary survey would be fantastic. It is our constant complaint that early stages of mental illness in the majority of cases pass unnoticed or are misinterpreted by both the patient and his friends. When a stage arrives at which the friends take action, there is seldom any kind of doubt that the patient is mentally deranged; no further observation is needed to establish the nature

of the malady, and the sooner consistent and uninterrupted treatment begins, the better. It is in a very small number of cases that any doubt arises or in which prolonged observation is indicated. To send every case, "public or private," to an "observation ward" would be to herd together in unconscionable fashion all sorts of persons who should decidedly not be together in the same wards, or, indeed, in "wards" at all; unless the term "observation ward" is to be so extended as to imply a mental hospital so equipped that patients could be classified according to their symptoms and placed some in one ward or private room and some in others. Expense alone would forbid such a mode of dealing with cases for the sole purpose of "observation."

A further suggestion, involving considerable cost, is that the opinion of an independent alienist should be sought in all cases in which a patient is considered to have mental symptoms. It may again be pointed out that in most cases the symptoms are as plain as a pike-staff to any layman, and it is just because they are so plain that the relatives have been moved to act. It is only in a very small proportion of cases that, so far as certification to facts indicating mental disorder is concerned, the opinion of a specialist is desirable. Another suggestion is that the patient should see his certificates. I am inclined to wonder if the author of the suggestion makes any distinction between the normal and the disordered mind. If a patient is capable of cognition of a certificate and can appreciate the character of the data upon which it is founded, he cannot, in most cases, be regarded as insane. If I certify that a patient is confused and disorientated, it means that his perceptions are too disordered to understand what a certificate is; or if I certify that he has delusions, it means that certain of his thoughts, of very real validity to himself, are morbid and that he cannot think healthily. What point is there in showing certificates to such patients? A much more important point is one which anyone with a small knowledge of mental disorder should be able to understand—namely, that in many cases to show a certificate to a patient would be the worst possible treatment and would intensify the symptoms.

It is unhappily the case that bizarre views are often attractive to a very large section of the public, while commonplace facts are uninteresting. This may account for the non-appearance (up to the present date) of any letter in rebuttal. I am, however, sure that the suggestions made will not be acceptable to those of knowledge and experience.—I am, Sir, yours faithfully,

Harley-street, W., March 24th. E. D. MACNAMARA.

To the Editor of THE LANCET.

SIR,—Obviously there is a wide difference of opinion as to the status of certificates of insanity. Dr. R. Eager seems to imply that the "grounds" of certification should be concealed from patients for fear of directing their resentment against the medical men who certified them, and he suggests that this view is general in the profession. Of course, as you pointed out in a leading article, these certificates are not the means of continued detention, and so, perhaps, are not very important, but I cannot believe that a rule of secrecy is justified. It is not feasible to prevent paranoiacs and hypomaniacs from learning who certified them, and concealment of the reasons for certification merely lends colour to their mistrust. The feeling that he is being wrongly, or at least capriciously, dealt with and has therefore no security for future liberation, the lack of confidence in the asylum medical staff, and the lack of insight into his own abnormality, are the three points on which a certified patient is at a disadvantage compared with a voluntary one who seeks treatment from the physician he chooses. Perfect frankness is necessary to overcome these difficulties and to establish a therapeutic relationship with a certified patient. From the purely medical point of view, therefore, no less than from that of public policy, it would seem that the less secrecy the better.—I am, Sir, yours faithfully,

Perth, March 22nd, 1924. IAN D. SUTTIE, M.B.

THE FAMILIAL OCCURRENCE OF ADDISON'S (PERNICIOUS) ANÆMIA.

To the Editor of THE LANCET.

SIR,—In their paper on the Relationship of Some Hæmolytic Disorders to Pernicious Anæmia, published in THE LANCET of March 15th, Drs. P. N. Panton, A. G. Maitland-Jones, and G. Riddoch describe a case of probable pernicious anæmia, in which a history of the disease was obtained in two and, perhaps, three other members of the family, and they refer to other examples of the familial occurrence of the disease recorded by Bartlett, Patch, and Minot. I have been able to collect no less than 40 examples of familial Addison's (pernicious) anæmia from the literature and have met with two similar cases myself. I have also had a patient with subacute combined degeneration of the spinal cord, who eventually die from Addison's anæmia, whose grandfather, father, paternal uncle, and brother died of the anæmia, and another patient with this nervous disorder, associated with achlorhydria but no anæmia, whose grandfather died of Addison's anæmia, and Willson has recorded a similar case.

Two additional examples of familial Addison's anæmia have been described respectively by Faber and Schauman, in which other members of the family had achlorhydria but no anæmia. Among 16 families, of which one member was in Martius's clinic on account of pernicious anæmia and others were given test-meals, complete achlorhydria was discovered in one or more of the healthy members in 11 families. In two out of three patients with normal blood, who were under my care on account of other diseases, in whom a test-meal was given because a relative had died of Addison's anæmia, complete achlorhydria was discovered.

My own cases and those recorded by others do not show that familial cases of Addison's anæmia differ in any way from ordinary cases, as suggested by Panton and his colleagues as a possible explanation of the familial history in their anomalous case of anæmia.

These facts seem to me to be strong evidence in favour of the view that familial pernicious anæmia is a result of familial achlorhydria, which Albu and Jung have shown, and my own experience confirms, may exist quite apart from the occurrence of anæmia in the same family. A comparison between the frequency of achlorhydria in normal adults and the death-rate from Addison's anæmia of the adult population shows that about 1 in 6 of people over 20 with constitutional achylia ultimately develop the anæmia. It is therefore not surprising that more than one member of a family with constitutional achylia should sometimes develop Addison's anæmia, subacute combined degeneration of the cord, or both.

I am, Sir, yours faithfully,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, March 17th, 1924.

To the Editor of THE LANCET.

SIR,—I have read with great interest the important series of cases recorded in your issue of March 15th by Drs. Panton, Maitland-Jones, and Riddoch, but would venture to ask for some more coherent line of approach to the problems which they present. There are now on record quite a large number of curious types of blood disease, of each of which two or three examples have been described, but of which the pathology remains obscure. To these Dr. Panton and his collaborators add, amongst others, the clinical type described in their Group 1. The details given are brief but the syndrome appears to be characterised by a long course, anæmia, jaundice, hæmoglobinuria, thrombosis, and in Case 1 by sepsis and splenomegaly.

It is to the commentary on these cases that I wish to take exception on the grounds that it embodies a false line of approach. It opens with the query, "the question arises as to the category in which these two cases are to be placed," and three possible

categories are discussed. It is surely legitimate to point out that no critical examination of cases can be of value if it presupposes that they must be placed in some already existing category. This difficulty seems to have been apprehended by the authors, for on the next page we find the remark, "for the present we prefer to place the two cases here described in a separate category," but this is, unfortunately, followed by a definite statement on their pathology which lacks, as far as can be seen, any sort of support beyond mere conjecture. This statement is as follows:—

> "The difference, however, between this condition and pernicious anæmia is apparently *one of degree only*, the phases of slow blood destruction responsible for the relapses of pernicious anæmia being accentuated by short sharp bursts of blood destruction in which the quantity of hæmoglobin liberated is so large that it is excreted as such in the urine." (Italics are mine.)

The "slow blood destruction" of pernicious anæmia takes place in the portal system according to Hunter, whose work has not yet been controverted. The products of hæmolysis are accordingly trapped in the liver and iron is there deposited in large amount. It is now suggested that if only that hæmolysis can be shorter and sharper than usual, the products will pass the liver unchanged and be excreted through the kidneys. This seems rather improbable, and it is certainly a novel suggestion. It will also be noticed that the statement quoted assumes that the speed and amount of hæmolysis determine hæmoglobinuria. Most authors have thought that it is the site and not the amount of hæmolysis which matters, and they have given good reasons for their belief. Why are their findings tacitly assumed to be of no value?

The fifth group described in the paper consists of a single case. The commentary commences: "The diagnosis in this case would appear to rest between pernicious anæmia and acholuric jaundice, and if we confine ourselves to these alternatives the evidence favours that of pernicious anæmia." May I suggest that there is no particular reason why a patient who has had his spleen removed for acholuric jaundice and who has a strong family history of this condition should not later suffer from pernicious anæmia? This would appear to be the most obvious explanation of the facts set out, and it is hardly affected by the diagnosis of "pernicious anæmia" in two of his relatives since that term has quite often been applied to acholuric jaundice because of the similarity in the blood pictures.

Finally, I would ask that the term "pernicious anæmia" may be used with some definite meaning, either as applying solely to a particular blood picture (which is not specific to any one clinical condition) or else as applying only to a particular clinical entity (Hunter's, Addisonian or glossitic anæmia) of which the blood picture in question usually forms part. The failure to make this distinction renders valueless a diagnosis of pernicious anæmia alone and this difficulty frequently arises. My own habit is to restrict the unqualified term to the clinical entity, and I believe that this is generally convenient.

I am, Sir, yours faithfully,

Sevenoaks, Kent, March 19th, 1924. GORDON WARD.

DOCTORS AND ADVERTISING.

To the Editor of THE LANCET.

SIR,—My recent essay [1] has brought evidence of very general agreement with the expressed view that intelligent advertisement may be not only proper but even desirable, and that its recognition as advertisement is independent of the question of payment.

Among the interesting comments which have reached me are some which relate to an incidental reference made to the steady State encroachment upon the private practitioner's preserves; and certainly there seems a growing divergence between the material interests of the individual practitioner and of medical bureaucracy in its most intimate form, the municipal health officer. We resolutely bolt and bar the door to a State service but are apt to overlook the activities of the fluent gentleman with the jemmy at the basement window. I, too, share the belief that free antivenereal treatment is the "thin edge," adroitly chosen as calculated to enlist the sympathy of the well-intentioned but less well-informed, in addition to the customary support from "reformer" and "anti" elements.

I see no possible objection to Dr. Wansey Bayly's suggestion that the names of competent specialists be made more accessible to the public through a special register or the suitable adaptation of an existing publication. Such a list could readily be corrected by the General Medical Council, as a non-partisan tribunal, with whom it would rest to decide whether a proponent's opportunities and experience in a definite branch of practice had been such that he might properly style himself a specialist therein. I take it that Dr. Bayly did not intend to convey that, *training and experience apart*, only those who maintain a hospital connexion are eligible to be described as specialists, for such a restriction would be manifestly unfair, and carries a suggestion of vested right or proprietary interest reminiscent of less enlightened times. It might be susceptible of being so interpreted that those who for reasons of age, health, increasing practice, and so forth, have relinquished hospital connexion cease ipso facto to be specialists. The recent graduate might be eligible for description as a heart specialist, but not so the outstanding figure of contemporary British medicine.

I am, Sir, yours faithfully,

London, March 21st, 1924. H. D. L. SPENCE.

[1] THE LANCET, Feb. 23rd, p. 423.

THE WASSERMANN REACTION IN THE NEW-BORN.

To the Editor of THE LANCET.

SIR,—May I be permitted to make a comment upon your leading article on the Effect of Maternal Syphilis on the Death of the Child appearing on p. 608 of to-day's issue? There is a point with regard to the significance of the Wassermann reaction in the new-born child which, since it appears to have escaped your notice, I have, perhaps, not stated with sufficient clarity in my report to the Medical Research Council.[1] I refer to the fact that in the series of cases re-examined at intervals varying from three weeks to 20 months after birth very striking alterations in the Wassermann reaction were found. While those infants which had been born with a negative reaction remained negative, *the majority (over 90 per cent.) of those born with a positive reaction lost that positive reaction*, even though it was still obtainable in the blood of the mother.

This disappearance of a positive Wassermann in the infant is a phenomenon to which attention was drawn by P. Fildes in a report to the Local Government Board in 1915. As his interpretation of the significance of the Wassermann reaction in the new-born has been very largely overlooked, and, indeed, has been directly traversed by certain writers,[2] I think the confirmation of it in my series of cases is worthy of note. That there is need to emphasise this is demonstrated by the fact that you, Sir, to judge from the second last sentence in your article, appear to regard a record of a positive Wassermann reaction in an infant as a synonym for syphilitic infection.

As I have pointed out on p. 65 of the Report referred to, (*a*) a positive Wassermann reaction in a new-born infant is of no value in diagnosis, and (*b*) the incidence of congenital syphilis is very much less than many purely serological studies have indicated within recent years.

[1] Maternal Syphilis as a Cause of Death of the Fœtus and of the New-born Child. Special Reports, No. 82. H.M. Stationery Office. 1*s*. 6*d*.

[2] S. M. Ross and A. F. Wright: THE LANCET, 1921, i., 962.

The results of the considerable series of post-mortem examinations recorded in the Report not only support these contentions, but also demonstrate that many of the signs supposed to be characteristic of congenital syphilis are quite inconstant in their presence in definitely syphilitic infants, while others are not confined to syphilitic cases. Finally, may I say that the clinical examination of the infants which have been followed up confirms the conclusion that a *positive Wassermann reaction in the child at birth cannot be taken as an indication that the infant is syphilitic.*—I am, Sir, yours faithfully,

Glasgow, March 22nd, 1924. J. N. CRUICKSHANK.

*** We are glad to publish Dr. Cruickshank's letter, since in our leading article it was not possible to take up more than a few of the interesting results obtained from his exhaustive inquiry. The interpretation of the Wassermann reaction in the newly-born is, as Dr. Cruickshank contends, a point around which controversy has centred, and we pointed out earlier in the article to which he refers that he, as well as other workers, have found it to be untrustworthy as an indication of infection.—ED. L.

A CRITICAL EXAMINATION OF PSYCHO-ANALYSIS.

To the Editor of THE LANCET.

SIR,—The review of my book with this title in your issue of Feb. 16th has only just come to my notice. Your reviewer charges me with arguing in a circle. He says: "Many observers have found themselves obliged to assume that mental processes take place without the subject being aware of them, and the author's dismissal of this assumption as being nonsensical is a *petitio principii*, though he tells us that psycho-analysts produce not a shred of proof, only assertions." I do not merely *tell* my readers this, but I give actual examples, where Freud makes an assertion and defends it on the ground of plausibility, and then on the next page calls it a "fact," or says: "as I have shown, or demonstrated, &c." Where, then, is the *petitio principii?* I cannot philosophically disprove the existence of the "unconscious" any more than your reviewer can disprove the existence of a green cow walking on its horns on the other side of the moon, but that does not prove the existence of either the "unconscious" or of the green cow. Wundt, Wm. James, Ziehen, Külpe, and many others have shown that the assumption of an unconscious is quite unnecessary.

If psycho-analysts were to agree that by "unconscious" nothing else is meant than neurone-dispositions there would be little to quarrel about. However, what appears to me far more important, and what psycho-analysts, as well as your reviewer, are most careful to avoid, is the fact that I have shown, I believe conclusively, that their methods of penetrating into the assumed "unconscious" are fallacious. Psycho-analysts always forget the control experiments (vide pp. 95 sq. and 214 sq.). Your reviewer also complains that I mention no references for the statement that "some authorities have pronounced themselves against this method (of reviving the lost memories of painful experiences) in no equivocal manner." I gave, however, an abstract of Pierre Janet's case of Marie which confirms my contention, and Otto Binswanger "Die Hysterie" (Wien, 1904), pp. 908–910, is especially emphatic on this point. After referring to the views of v. Krafft-Ebing, Löwenfeld, and Brodmann, Binswanger concludes: "The revival of old memories has the contrary effect. An emotional storm is unfettered whose consequences are quite incalculable, which not only intensifies symptoms already present, but also produces new ones." I am, Sir, yours faithfully,

A. WOHLGEMUTH.

Shortlands, Kent, March 22nd, 1924.

*** Dr. Wohlgemuth's courteous letter largely confirms the review, while he has, of course, a perfect right to his own opinions.—ED. L.

MEASLES INFECTION: REASONABLE METHODS OF PREVENTION.

To the Editor of THE LANCET.

SIR,—The Sydenham District Medical Society, which is composed of general practitioners mostly of many years' standing, at a recent meeting considered the question of the spread of infectious diseases and came to the following conclusion:—

"There is no evidence of second attacks of measles or of the conveyance of the disease by healthy immune individuals sufficient to justify the existence of a rule forbidding any person from attending school or office from a house in which there is a case of the disease provided satisfactory medical evidence of a previous attack is forthcoming."

This opinion was agreed to unanimously, and I was requested to communicate it to you with the hope that a discussion of the subject by a wider circle might lead to the abolition of rules which are probably unnecessary and often entail considerable hardships on individuals.

I am, Sir, yours faithfully,

H. M. STEWART,
Hon. Secretary, Sydenham District Medical Society.

Dulwich, March 24th, 1924.

TESTS FOR CURE OF GONORRHŒA IN WOMEN.

To the Editor of THE LANCET.

SIR,—I was much interested in the comments of Dr. P. Fildes and Dr. G. T. Western on my paper. Briefly, they state that in some 200 examinations of cultures and smears in women they found 25 per cent. positive in culture, and 20 per cent. in smear. From this they draw the conclusion that cultures are preferable to smears as a routine test.

I am somewhat puzzled as to what exactly the figures quoted by them mean. As my paper was on "Tests for Cure"—and this appears above their letter—it reads as if cases considered clinically cured at the London Hospital, and sent up for a bacteriological test, were found still infected in these proportions. I cannot think Drs. Fildes and Western can possibly mean this; but that, writing with the detachment of bacteriologists when clinical matters are concerned, they are really stating that in some 200 specimens, examined at various stages of the disease, they got the results mentioned. No indication is given as to how many patients these 200 results represent—whether 20 cases examined 10 times, or 200 examined once; nor do they say if the smears were taken in the manner indicated, and with the precautions suggested by me, in the paper criticised. I am still unrepentant in my statement that I have found smears preferable to cultures in testing for the presence of the gonococcus in women.

This statement is the result of the examination of some thousands of women in all stages of the disease, and has been arrived at after a good many years of observation. I have had runs of success with cultures. I have seen runs of failures with smears. A new clinical assistant or house surgeon until drilled often got extremely poor results. I hold no brief for smears taken in any way except as indicated in my papers. I should like Drs. Fildes and Western, therefore, to give smears another trial following that technique.

The whole subject is such a difficult one, the risk of missing the gonococcus, using every known precaution, is still so great, that no method should be neglected which has given success in the hands of others. If Drs. Fildes and Western will examine 1000 women in the manner used by me, and compare the percentage success with cultural results, they may alter their opinion.

I am, Sir, yours faithfully,

J. JOHNSTON ABRAHAM.

Harley-street, W., March 21st, 1924.

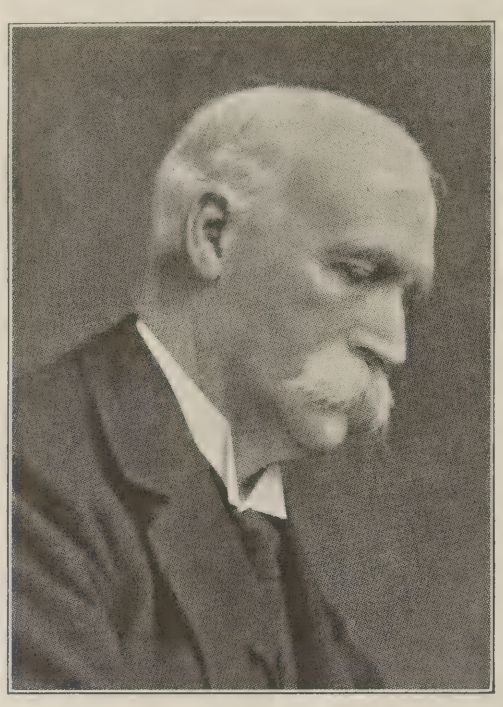
Obituary.

SIR WILLIAM MACEWEN, F.R.C.S. ENG. & IREL., F.R.F.P.S. GLASG., F.R.S., D.C.L., &C., C.B.,

REGIUS PROFESSOR OF SURGERY, UNIVERSITY OF GLASGOW.

WE much regret to announce the death of the famous surgeon and professional leader, Sir William Macewen, which occurred on Saturday last, March 22nd, at his residence in Glasgow, in his seventy-sixth year.

William Macewen was born on June 22nd, 1848, his father being in the mercantile marine, and at one time master of a yacht, while he was also engaged in commercial undertakings in Rothesay. The great surgeon was the youngest child of a large family and his



SIR WILLIAM MACEWEN.

early life was passed in modest circles. After elementary instruction in Rothesay, he completed his education at the Collegiate School at Glasgow before entering the University. Without obtaining academic honours he worked steadily, and by the time he was of age he had graduated at the University as M.B., C.M. After holding residential appointments, including the house surgeoncy at the Royal Infirmary under Sir George Macleod, he proceeded in 1872 to the M.D. degree, and then for a period he studied at some of the big schools on the continent. Returning to Glasgow he went into private practice and had excellent experience in dispensary work. His chance came when he was elected assistant surgeon to the Royal Infirmary. He had now become an ardent disciple of Listerian principles, perceiving that in every direction they promised untold developments in surgical theory and practice. He had benefited alike by his own practical work and by the excellent training at the University, which enabled him to absorb the lessons and take advantage of the opportunities which the rising science of bacteriology held out. Allan Thompson, Andrew Buchanan, and William Tennant Gairdner were among his teachers, while Lister was engaged in his famous work, first at Glasgow and later at Edinburgh, at the very period when Macewen was inaugurating his great career.

Macewen seems to have been always, though deeply indebted to his training, an independent thinker, and it was during his period of general dispensary practice in Glasgow that he laid the foundation of his clinical knowledge and obtained the resourcefulness that ever marked his practice. His appointment to the Royal Infirmary gave him an opening, which was made wider in a very short period by his becoming in 1877 full surgeon to the institution. This post he held for 15 years, when he succeeded Sir George Macleod, his former teacher, as Regius Professor of Surgery. On the scene of Lister's earliest triumphs—which, it may be added, attracted at first no great attention—Macewen steadily carried out a wonderful work, developing and modifying the antiseptic treatment and becoming a pioneer in particular of brain surgery. The work of Hughlings Jackson and David Ferrier, pre-eminently among others, had brought out the main principles of brain localisation, and Macewen was amongst the first to envisage the possibilities which this knowledge offered under proper application of aseptic methods.

He was probably the first to practise brain surgery in the modern sense of the word, as apart from trephining for injury. In the *Glasgow Medical Journal* of 1879 he published a paper describing how a tumour of the dura mater which had been attended with convulsions was removed after opening the skull with completely satisfactory results. Further contributions followed in THE LANCET on similar work, a paper on monoplegia of the left arm and leg due to cortical lesion forming a good example of his clinical methods; and in 1883 he delivered an address at a meeting in Glasgow of the British Medical Association, taking as his subject the surgery of the brain and spinal cord, which placed him at once in the front rank of surgery throughout the world. The whole subject of brain surgery, as well as his own personal share in its development, was made the subject of his presidential address before the Association in 1922. This contribution to medical science and medical history was published in the *British Medical Journal* and in our own columns, and showed alike how brain surgery had developed pari passu with the efforts of such bold thinkers and expert workers as Ferrier, Horsley, Beevor, Godlee, Gowers, Mott, and Ballance, and how great and independent a place the speaker had himself taken in the work.

Although Macewen's name is mainly associated with brain surgery he was in no sense a specialist, and, as a matter of fact, his earliest work to attract outside attention was in the direction of orthopædics. As early as 1878 a paper was published by him in our columns upon antiseptic osteotomy for genu valgum and genu varum, and other papers followed upon the surgical treatment of osseous deformities and their remedy. He was an innovator in the correction of faulty union of long bones, his method of refracture necessitating a new technique. His success in osteotomies for defective limbs brought about valuable modifications in the operative procedure for various forms of talipes, previously met in an unsatisfactory manner by tenotomies, while his work in bone transplantation was also original, and, both in his hands and as developed in the hands of others, has proved a valuable branch of conservative surgery. A monograph which he published some ten years ago on the development of bones proved the independence and boldness of his views in this province of his science, and the same features marked his work on the surgery of the lung, and the technique which he laid down for dealing with various forms of hernia.

As professor of surgery in Glasgow, Macewen was a great and practical success. He was a man with large views and unsparing of his own time, strength, and money, and he soon got around him brilliant assistants and eager pupils, while honours accumulated thick upon him. Elected a Fellow of the Royal Society, he received honorary Fellowships from the Royal Colleges of Surgeons both in England and in Ireland; he was a D.Sc. of Oxford and Dublin, a D.C.L. of Durham, and an LL.D. of Glasgow and Liverpool. He was elected to the honorary membership of Imperial or Royal Academies and national scientific

societies in France, Germany, Austria, Hungary, Italy, Russia, and the United States, and became President of the International Association of Surgery in 1921. In the following year he was knighted and was elected President of the British Medical Association, being largely responsible for the great success which attended the meeting at Glasgow in that year. He was Honorary Surgeon to the King in Scotland. He received a knighthood in 1902, and was also appointed C.B.

During the war he was one of the first consultants to be appointed by the medical department of the Royal Navy, and was associated from the beginning with the scheme for the establishment of the Home for Limbless Sailors and Soldiers at Erskine. His last journey was undertaken as ambassador of the British Medical Association to the Australasian Medical Congress at Melbourne in November, 1923.

In Macewen the scientific world has lost a great man, who arrived at the head of a learned profession with no extraneous advantages, but by unflinching study and a brave use of unfettered judgment. And his personal appearance coincided exactly with this character. Very tall, handsome, and grave, he commanded without seeking it the immediate attention which philosophers less well endowed physically must struggle to obtain. We reproduce with permission the portrait which appeared in the *British Medical Journal* in October, 1922.

Sir William Macewen married Mary, daughter of Hugh Allan, of Govanhill, by whom he had six children, three daughters and three sons. And it may be mentioned that all the sons entered the medical profession, two being decorated for war work. He was throughout his busy life devoted to the countryside of his birth, and it was a source of real gratification to him when the freedom of the borough of Rothesay was conferred upon him in the courtyard of the ancient castle ruins. In his later years he had purchased a property in Kingarth, where he became a scientific and successful farmer as well as a keen researcher on many biological and veterinary problems. A good example of his fruitful interest in such by-paths was furnished by his study of the antlers of the deer, which was an elaborate essay on bone physiology.

HENRY RUNDLE, F.R.C.S. ENG.

Henry Rundle, consulting surgeon to the Royal Portsmouth Hospital, died on March 19th at Southsea in his eightieth year. Rundle began his medical study as apprentice to the late Mr. W. J. Square, of Plymouth, going on to St. Bartholomew's Hospital, London, whence he became M.R.C.S. Eng. in 1865 and F.R.C.S. in 1870. In the latter year the British Red Cross Society sent out six surgeons to the aid of sick and wounded on either side in the Franco-Prussian War, and Rundle was selected as one of them, proceeding with Mr. W. E. B. Atthill and Mr. J. C. Galton to Berlin first and then to the "Alice" Hospital at Darmstadt, founded under the auspices of Princess Louise of Hesse-Darmstadt (Princess Alice of England), which provided a reserve hospital for the Hessian Division of the Prussian Army. Rundle also served for a time in the neighbourhood of Strasbourg, towards the end of the historic siege of that city, which he entered very shortly after its capitulation. For his services to the wounded of both German and French armies, Rundle received the German War Medal, the Hessian Cross, and also the French War Medal. He was probably the only recipient of both French and German war medals in Europe.

On returning to England after the war Rundle became house surgeon to the Royal Hants County Hospital at Winchester, proceeding thence to Southsea, where he settled down in general practice and commenced his long association with the Royal Portsmouth Hospital, first as assistant surgeon and then as surgeon, retiring in 1908 but remaining in a consulting capacity. His health was latterly feeble and he led a quiet retired life—he was a bachelor—during the last 14 or 15 years, but retained his mental vigour to the end. He was the author of "With the Red Cross in the Franco-German War," and for many years a valued contributor to our columns on matters of local interest.

Of a peculiarly honest, plain-spoken, and kindly disposition, Henry Rundle made firm friendships and won general respect and esteem. The Royal Portsmouth Hospital loses in him a devoted friend.

THOMAS HILL JAMIESON, M.D., M.R.C.P. EDIN.

Dr. T. H. Jamieson, Deputy Commissioner of Medical Services in Tropical Disease under the Ministry of Pensions, whose death occurred recently in London at the age of 50, was a graduate of the University of Edinburgh, where he qualified M.B., C.M. in 1894, and there later he gained the degree of M.D. He also was admitted a Member of the Royal College of Physicians of Edinburgh in 1915. After holding his first appointments as house surgeon to the Huddersfield Infirmary and then to the Children's Hospital, Liverpool, he went to the Far East and settled in Penang, Straits Settlements, where he built up an extensive practice. After many years of strenuous work in the tropics his health began to fail, and he finally returned to England in 1917. He was rejected for service abroad, but was appointed to the Fourth London General Hospital R.A.M.C.(T.) as specialist in malaria and other tropical diseases. In 1919, having obtained the D.P.H. London, he joined the medical staff of the Ministry of Pensions, where, in virtue of his special knowledge of tropical disease, he held the appointment of deputy commissioner with administrative charge of the tropical clinics in the S.E. region. Later he became visiting physician to the Ministry's Hospital at Orpington, Kent, and to Queen's Hospital, Sidcup. For his services he gained the honour of M.B.E.

A friend on the Pensions medical staff writes:—

"Dr. Jamieson was outstanding in his clinical judgment and acumen, and enthusiastic in all his work. By his unfailing courtesy and kindness he won the confidence of colleagues, staff, and patients, many of whom at their own request attended his funeral service at Golders Green. His broad sympathies and wide outlook on the problems of the day, with all the political questions so immediately affecting national life, made him a companion to be sought and prized. Politically he inclined to many of the aspirations of the Labour Party."

To his widow we extend our sincere sympathy.

HERBERT LEYLAND SACKETT, M.B., B.S. LOND., F.R.C.S. ENG.

Mr. H. L. Sackett, clinical assistant, St. Bartholomew's Hospital, died on March 21st after a very brief illness, at the age of 30. Vigorously pursuing his surgical work until midnight on March 13th, he complained of feeling very ill and had a rigor. It was then discovered that one thumb was inflamed. Treatment was immediately carried out, but despite all efforts the trail of septicæmic symptoms followed. The tragedy was heightened by the fact that in another ward of the hospital lay his father, the Rev. Walter Sackett, suffering from erysipelas. Father and son died within a few hours of each other. As a boy Mr. Sackett suffered from spinal trouble and for months laid recumbent. During this time his ever active mind was gleaning lore of every kind. His years at St. Bartholomew's were years of triumph. As a student he won the Bentley prize; he became a house surgeon, and later intern midwifery assistant. Last year he gained his F.R.C.S., obtained a research scholarship, and has been engaged for many months in original work on intestinal obstruction. In January of this year he was appointed a surgical clinical assistant. He was for more than two years editor of *St. Bartholomew's Hospital Journal*, and as a student was President of the Christian Union.

Mr. Sackett was not only a surgeon of great promise, but a man of the highest type. His kindness endeared him to his patients, and his amazing thoroughness and devotion to duty caused him to be deeply respected by all who came in touch with him.

Medical News.

UNIVERSITY OF OXFORD: *Radcliffe Travelling Fellowship.*—The Master and Fellows of University College announce that the trustees have elected Charles Frederick Terence East, M.A., B.M., B.Ch., M.R.C.P., New College and King's College Hospital, to a Radcliffe Travelling Fellowship of £300 for two years.

The following degrees in medicine have recently been conferred :—

Doctor of Medicine.—S. C. Dyke and J. J. Conybeare.
Bachelor of Medicine.—H. A. Robertson, E. B. Strauss, Jean Orr-Ewing, B. G. Scholefield, and R. V. Facey.

UNIVERSITY OF LIVERPOOL.—At examinations held recently the following candidates were successful :—

FINAL EXAMINATION FOR DEGREES OF M.B. AND CH.B.

Part I.—M. M. F. Arthur, Ethel Barrow, E. I. Bieber, H. M. Boston, G. E. Church, N. L. Corkill, O. Dawood, J. L. Donnelly, F. R. Faux, Dorothy A. Gough, J. Graham, R. I. Greenshields, J. Hatton, E. Hughes (with distinction), F. P. Irvine, D. Katz, B. Kay, J. E. S. Lloyd, W. J. Lloyd, H. McGrath, Isabel McKee, D. J. T. Magowan, D. Roberts, J. Tarshish, I. Thomas, and J. E. Walker.

Part II.—T. A. Clarke, N. J. Crawford, H. L. Cullen, I. Gordon, A. J. Goss, Catherine E. I. Greenshields, Sarah Leigh, G. W. Paton, F. B. Shevlin, and B. J. S. de Villiers.

DIPLOMA IN PUBLIC HEALTH.

A. C. Crawford and Mary A. Thomas.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

J. D. Ingram, J. S. Kellett-Smith, W. J. MacHugh, H. Miller, and R. E. Sadleir.

UNIVERSITY OF DURHAM: *Faculty of Medicine.*—At recent examinations the following candidates were successful :—

THIRD EXAMINATION FOR LICENCE IN DENTAL SURGERY.

Anatomy, Physiology, and Histology; Dental Anatomy, Dental Histology, and Dental Materia Medica.—Thomas E. Coulson, Lionel G. Dewar, Wilfred A. Gale, Frederick J. Gilbertson, Wilton L. Milburn, Robert Moody, and Norman Wilkinson.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated :—

Surgery.—A. Kotbi, St. Mary's Hospital, and D. G. Robinson, Guy's and Charing Cross Hospitals.
Medicine.—F. H. Armanious, St. Thomas's Hospital; M. K. El Khadem, Liverpool; and W. H. G. M. Ling, Edinburgh and St. Mary's Hospital.
Forensic Medicine.—E. J. Creais, St. Mary's Hospital; C. E. Donaldson, Cambridge and St. Mary's Hospital; R. D. Jones, Edinburgh and Middlesex Hospital; W. H. G. M. Ling, Edinburgh and St. Mary's Hospital; J. P. McGuire, St. Mary's Hospital; J. G. E. Vachell, Cambridge and St. George's Hospital; and A. J. Vickery, St. Mary's Hospital.
Midwifery.—W. B. Arnold and J. O. W. Bland, St. George's Hospital; W. H. G. M. Ling, Edinburgh and St. Mary's Hospital; and J. G. E. Vachell, Cambridge and St. George's Hospital.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: M. K. El Khadem, W. H. G. M. Ling, and A. J. Vickery.

BRITISH MEDICAL ASSOCIATION: SCHOLARSHIPS AND GRANTS.—The Council of the British Medical Association is prepared to receive applications for *Research Scholarships* as follows :

1. An Ernest Hart Memorial Scholarship of the value of £200 per annum, for the study of some subject in the department of State medicine.

2. Three Research Scholarships, each of the value of £150 per annum, for research into some subject relating to the causation, prevention, or treatment of disease.

Each scholarship is tenable for one year, commencing on Oct. 1st, 1924. A scholar may be re-appointed for not more than two additional terms, and may hold a junior appointment at a university, medical school, or hospital, provided the duties of such appointment do not interfere with his work as a scholar.

Grants.—The Council is also prepared to receive applications for grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose as subjects of investigation problems directly related to practical medicine.

Applications for scholarships and grants should be made not later than June 7th. Applicants are required to furnish the names of three referees competent to speak as to their capacity. The conditions are fully stated in the regulations, a copy of which will be supplied on application to the Medical Secretary of the Association, 429, Strand, London, W.C. 2.

HARNETT *v.* BOND AND ADAM.—The date of the hearing of the appeal in this case has been postponed until April 7th.

THE Cambridge University Press will shortly publish a reprint, in its original form, of Sir Michael Foster's "Lectures on the History of Physiology during the Sixteenth, Seventeenth, and Eighteenth Centuries," which has been out of print since 1922.

QUEEN'S UNIVERSITY (BELFAST) CLUB, LONDON.—A dinner will be held in the Connaught Rooms, Great Queen-street, London, W.C. 2, on Thursday, April 10th, at 7.30 for 8 o'clock. Prof. Thomas Sinclair, President of the Club, will take the chair. The charge for the dinner will be 12*s.* 6*d.*, inclusive of gratuities but exclusive of wines, which sum will be collected during the evening. Old students intending to be present are requested to notify the hon. secretaries at 152, Harley-street, London, W., to this effect not later than April 7th.

CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS.—The members' congress will be held from April 3rd–5th. On April 3rd, at 11 A.M., Professor Winifred Cullis will lecture on Internal Secretions: Integration of the Body by Chemical Agencies, and at 6 P.M. Miss A. M. Hallam will lecture on Psychology in Every-day Life, at the Wigmore Hall, Wigmore-street, London, W. 1. At 3 P.M. representative work in the various departments of Chelsea College of Physical Education will be shown to members. On April 4th, at 10.30 A.M., demonstrations of treatments will be given in the Botanical Theatre, University College, Gower-street, London, W.C. 1. At 2.30 P.M. a lecture-demonstration on patients under treatment will be given by Mr. W. H. Trethowan in the Physiological Theatre, Guy's Hospital, S.E. 1, and at 6 P.M. Mr. L. E. Barrington-Ward, F.R.C.S., will lecture on Pseudo-paralysis in Children at the Wigmore Hall. On April 5th, at 11 A.M., Dr. J. B. Mennell will speak on Post-maternity Work, also at the Wigmore Hall. The annual meeting of the Society will be held on April 5th, at 2.30 P.M., at the Court House Restaurant, 1, Marylebone-lane, Oxford-street, W. 1.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The tenth annual conference will be held in London on July 3rd and 4th. The main subject under consideration will be the Part Played by Training Colonies in the Treatment of Tuberculosis, and the conference will take the form of a practical demonstration of the work carried out at the training colony, founded and maintained by the National Association at Burrow Hill, Frimley. This colony is included in the scheme of the Ministry of Pensions, and has 60 places for the treatment and training of tuberculous ex-Service men who have already received sanatorium treatment. The courses of training comprise: (*a*) carpentry, (*b*) market gardening, poultry, pig and bee keeping, including light farm work. There is also a sanatorium block of 20 additional beds. Arrangements will be made for the conveyance of members of the conference from London to the colony. After the demonstration a discussion will be opened by Dr. A. H. Macpherson, and the discussion will be continued on July 4th at the Robert Barnes Hall, 1, Wimpole-street, London, W. 1. Further particulars may be obtained from the Secretary of the Association, at 20, Hanover-square, London, W. 1.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The London Temperance Hospital, Hampstead-road, as previously announced, is giving a two weeks' intensive course from Monday, March 31st, to Saturday, April 12th, consisting of practical demonstrations each morning from 10.15 to 12.15, and in the afternoon from 2 to 4 P.M. ward rounds and out-patient clinic. Lectures, open to members of the profession, will be given daily at 4.30 P.M., the first being given by Sir Humphry Rolleston on March 31st on Jaundice. Other lecturers for the week are: Dr. Porter Parkinson, Heart Disease in Children; Mr. Herbert Paterson, Surgical Treatment of Dyspepsia; Dr. David Somerville, Gastro-enterology (I.); and Mr. Lawson Whale, Otorrhœa and its Treatment. Special demonstrations will be given on Fevers on Thursday morning at the North-Western Fever Hospital, on Mental Diseases at Bethlem Royal Hospital on Saturday morning, and in Ophthalmology at the Royal Westminster Ophthalmic Hospital in the afternoon. Beginning on March 31st a three weeks' course in Ophthalmology will be held at the Royal Westminster Ophthalmic Hospital. Clinical instruction will be given every afternoon from 2 P.M., and special demonstrations in medical ophthalmology and methods of examination will be given on Tuesdays and Thursdays. Copies of the syllabus with further information as to the above courses can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole-street, London, W. 1.

WELFARE OF THE DEAF.—An important conference of representatives of schools and missions interested in the welfare of the deaf was held under the presidency of Lord Charnwood at the Kingsway Hall, London, on March 19th. Resolutions were passed emphasising the need for the reconstitution of the National Bureau for Promoting the General Welfare of the Deaf on broader lines, so that the claims of the deaf might be authoritatively expressed and nationally met as have been those of the blind, and suggesting that the name of the bureau be changed to the National Institute for the Deaf. Lord Charnwood pointed out the need, in the interests of the general community as well as of the deaf themselves, of some central body which could voice the requirements of the deaf. Mr. A. J. Story called attention to the neglect by the State of the deaf who, he said, were worse off than the blind, for nothing was done for them after the age of 16. A central body should be able to apply pressure on the Government. Mr. T. Mardy Jones, M.P., who said that his interest in the deaf had been stimulated as a result of the conference, advocated the formation of a Parliamentary group in the House of Commons, when ways and means would soon be found of doing something substantial for the deaf. It was announced that both the Prime Minister and the Minister of Health had expressed their sympathy in the conference. Dr. A. Eichholz was present as representing Mr. Wheatley. A conference to draw up a new constitution will be convened at a later date.

TUNBRIDGE WELLS GENERAL HOSPITAL. — The fund earmarked for the purpose of extending this hospital now stands at £8000, and it was announced at the recent annual meeting of the governors that when the figure reached £10,000 plans would be considered. The need for provision for paying patients was emphasised, and an appeal was made for a speedy realisation of the sum needed. During 1923 the number of in-patients constituted a record—viz., 1304, including 525 women, 519 men, and 260 children, a total of 124 in excess of the previous year. The out-patients numbered 4765, an increase of 334 over 1922. The theatre operations totalled 705, and in addition 445 operations were performed in the out-patients' department under a general anæsthetic. There were also 404 dental cases, 24,197 treatments in the electrical department, and 1211 X ray diagnosis and screen examinations. The governors intimated that they had decided to improve and to add to the equipment of the electrical department at a cost of nearly £500, the X ray apparatus to be so improved that treatment for certain cases of cancer would be possible; and that a new expense had been incurred by the insulin treatment for diabetes. The total income amounted to £12,794 17*s.* 6*d.*, and the expenditure £12,990 2*s.* 5*d.*, the excess of expenditure over income being £194 5*s.* 11*d.* It was pointed out that under the conditions now existing an income of £13,000 per annum was needed to run the hospital efficiently. The patients treated during 1923 represented no fewer than 87 towns and villages.

THE SCHICK TEST AT BRIGHTON.—At a sessional meeting of the Royal Sanitary Institute held on March 14th Dr. Duncan Forbes read a paper on the Schick Test and Immunisation against Diphtheria. He mentioned that during the last 23 years there were 5500 cases of diphtheria and 350 deaths in Brighton. Most of the cases occurred between the ages of 5 and 10 years, and most of the deaths also occurred at that time. While the health services could do much in preventing the spread of the disease in families, in residential schools, and, more doubtfully, in day schools, they had been able to do little to prevent the occurrence of epidemics, and it was, therefore, necessary to look for some new means of combating the disease. The most hopeful of recent discoveries was, Dr. Forbes considered, immunisation by toxin-antitoxin. The first task was to discover who were susceptible and who were not susceptible, and this, Dr. Forbes said, could be foretold in many cases by a careful study of the reaction of the Schick test, and steps taken to prevent any great reaction. The cost of testing 50 children with the Schick test worked out at 12*s.* 6*d.*, and to give protection to one child with toxin-antitoxin cost 3*s.* apart from the doctor's time. It would, therefore, Dr. Forbes declared, cost some £300 each year to immunise all Brighton's 2000 one-year-olds, but the cost of such immunisation would be balanced by the saving of over ten lives each year and by all the money that would be saved from nursing in hospital and at home through rather serious illnesses, so that economically it was well worth while immunising even small numbers of children. In Brighton free immunisation was offered to children in the residential institutions, and any mother applying at an infant welfare centre could have her children immunised free of charge. The nurses at the fever hospital, particularly the probationers, were now protected against the disease. Dr. A. Greenwood disagreed with a suggestion by Dr. Forbes, that in applying the Schick test it should not be necessary to consult the parents of the children to be treated, and expressed the opinion that if the parents objected it was possible that an action for assault might lie against the doctor. Dr. Greenwood spoke of the difficulties in carrying out medical inspection of secondary school scholars owing to the objection of parents, and felt sure a vigorous opposition would follow in the case of the Schick test.—Dr. F. C. Linton, Dr. H. P. Newsholme, and Dr. Hugh Stott also took part in the discussion.

Mr. H. D. Gillies is proceeding on the invitation of the Danish Government to Copenhagen for the purpose of treating by prosthesis, or in accordance with their condition, the officers and men who were wounded by the explosion on the Danish cruiser *Geyser* last summer.

NAVAL MEDICAL COMPASSIONATE FUND.—A meeting of the subscribers of this Fund will be held at 11.30 A.M. on April 25th, at the Medical Department of the Navy, 68, Victoria-street, S.W. 1, to elect six directors of the Fund.

THE LATE DR. R. FITZMAURICE. — Dr. Richard Fitzmaurice, who died at Littlehampton on March 11th, aged 72, had lived in retirement since 1909, in which year he completed a quarter of a century's work as medical officer and public vaccinator in the Lindfield district of the Cuckfield Union in Sussex. He was educated at Queen's College, Cork, and the University of Edinburgh, where he qualified L.R.C.P., L.R.C.S. in 1884, and in the same year went to reside at Lindfield. Dr. Fitzmaurice was a laughter-loving Irishman, and the poor folk who formed the main bulk of his patients found in him not only a kindly parish doctor but a real friend.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

National Health Insurance (Cost of Medical Benefit) Bill.

An explanatory memorandum issued with this Bill reads as follows :—

The object of this Bill is to provide the moneys required to meet the balance of the cost of medical benefit and administration beyond the sums provided by s. 7 of the National Health Insurance Act, 1920. For the period from the 1st April, 1922, to the 31st December, 1923, this balance was provided mainly out of the funds of approved societies in accordance with the provisions of the National Health Insurance Act, 1922.

	s.	*d.*
The total cost of medical benefit in England from 1st January, 1924, including doctors' capitation fee, cost of drugs, doctors' travelling allowances, and certain other minor items will be (per insured person per annum)	11	10½
Towards this there is provided from funds of the approved societies by s. 7 of the National Health Insurance Act, 1920, a sum of (per insured person per annum)	9	6
Leaving a balance of (per insured person per annum)	2	4½

Clause 1 (1) (*a*) and (*b*) provide for the payment of this balance for the three years 1924 to 1926.

Clause 1 (2) provides that this balance is to be found from the following sources :—

	s.	*d.*
(*a*) Out of the funds of approved societies, &c. ..	0	2
(*b*) Out of moneys in the Central Fund derived from the unclaimed balance of sums received from the sale of National Health Insurance Stamps..	1	8¾
(*c*) Out of the interest earned on the proportion of insurance funds retained in the National Health Insurance Fund (Investment) Account beyond the prescribed rate (4½ per cent.) credited on moneys standing in that Account	0	6
	2	4½

Under section 3 of the National Insurance Act, 1911, two-ninths of the above sums are payable out of moneys provided by Parliament, the remaining seven-ninths being derived from the contributions out of which the above funds are made up.

Clause 2 provides for the payment into the Central Fund of a further sum of £100,000 from the unclaimed balance in the Stamps Sales Account over and above the proportion of that balance which is normally paid into that fund. This is required in order to enable the sums under Clause 1 (2) (*b*) to be met out of the Central Fund.

Clause 3 re-enacts, as from 1st January, 1923, to 31st December, 1925, the provisions of section 3 of the National Health Insurance Act, 1922, which lapsed on 31st December, 1922, and under which assistance was given to approved societies from the unclaimed balance in the Stamps Sales Account to enable them to pay benefits to members who would otherwise have been suspended from benefit by reason of arrears due to prolonged unemployment.

Clause 4 provides for a corresponding payment to the Ministry of Labour for Northern Ireland out of the Central Fund, which is an international fund common to England, Scotland, Wales and Northern Ireland.

Clause 5 applies the Bill to Scotland and Wales with such modifications as are required in consequence of a difference in the cost of drugs, doctors' travelling allowances, and other minor items in those countries.

The total amounts to be provided in each year for the whole of Great Britain from the various sources under clauses 1 (2) and 5 (including the statutory grant of two-ninths from the Exchequer) are as follows :—

	£
(*a*) Out of the funds of approved societies, &c. ..	118,000
(*b*) Out of moneys in the Central Fund	1,266,000
(*c*) Out of interest income	378,000
	1,762,000

HOUSE OF LORDS.

TUESDAY, MARCH 25TH.

Dogs as a Subject of Medical Research.

Lord BANBURY moved the second reading of the Dogs' Protection Bill, having for its object the exemption of dogs from scientific experiments; in the course of his words he claimed THE LANCET as upholding the statement that dogs were not necessary for experiment. Lord KNUTSFORD moved the rejection of the Bill in an amusing speech in which he prophesied that other peers, especially interested in other animals, might make similar efforts for their exemption. Speaking of the ravages of distemper, Lord KNUTSFORD said that the Bill would stop all research on the subject, and that if dogs could speak he doubted whether they would seek the suggested exemption. Lord LAMBOURNE supported the Bill, when Lord MILDMAY, one of the three lay members of the Medical Research Council, opposed the measure in an excellent speech, in which he informed the House how research for organisms connected, for example, with distemper, foot-and-mouth disease, and swine fever, would be affected by the proposed restriction. Lord RAYLEIGH spoke against the Bill as setting up an obstacle in the way of those who were seeking to penetrate the secrets of disease; and the LORD CHANCELLOR announced that the Government would not favour the measure. Lord CURZON stated that experiments upon dogs had led to incalculable benefits in recent years, in regard particularly to discoveries in connexion with diabetes and rickets; while Lord PARMOOR announced that at the Medical Research Council inquiries were taking place into distemper, in which hopeful progress had been made.

The motion for the second reading of the Bill was rejected without a division.

HOUSE OF COMMONS.

TUESDAY, MARCH 18TH.

Medical Boards and Ex-Service Men.

Mr. FREDERICK GOULD asked the Minister of Pensions whether, in view of the dissatisfaction existing amongst ex-Service men arising from the under-assessment of their disability at the hands of medical boards, he would issue on behalf of his department a circular requesting a more sympathetic and even generous consideration of the cases coming before them for examination.—Mr. F. O. ROBERTS replied: I have no reason to believe that the assessments given by medical boards do not represent a fair and impartial judgment on the conditions of the disability as found on examination. On assuming office as Minister of Pensions I issued a communication to all Members of the Ministry Staff, including members of medical boards, reminding them that the work of the department should invariably be carried out in a spirit of the utmost consideration and sympathy.

WEDNESDAY, MARCH 19TH.

Stone-dusting and Health of Miners.

Mr. CHARLES EDWARDS asked the Secretary for Mines whether he had received complaints of the effects of stone-dusting on the health of miners; whether he was aware that there was no obligation on colliery owners to remove dust, but only to see that a certain proportion of stone-dust was maintained, and, consequently, instead of removing coal-dust stone-dust was constantly added, making travelling on haulage roads not only a nuisance but highly injurious to the health of the workpeople who had to use them; and whether he would request the committee now inquiring into the effects of stone-dust to go down some mine during working hours and whilst the roads were actually being used, so as to enable them to form an intelligent opinion of the magnitude of the evil and the necessity of discontinuing the same.—Mr. SHINWELL replied: I have received some such complaints, though they are rare. I think that my hon. friend has overlooked Section 6 of the General Regulations of July 30th, 1920, which requires that the floor of every travelling road shall be cleared of dust at regular intervals of time. There need be no fear that a committee, which includes Dr. Haldane and Dr. Collis, is without first-hand experience of working conditions underground.

Lead Poisoning in China and Earthenware Trades.

Lord HENRY CAVENDISH-BENTINCK asked the Home Secretary the number of cases of lead poisoning, and the number of fatal cases, in the china and earthenware trades during 1923, and also during January and February, 1924.—Mr. HENDERSON replied: The following are the particulars asked for :—

—	1923.		January and February, 1924.	
	Total No. of cases.	No. of deaths.	Total No. of cases.	No. of deaths.
China and earthenware trades	44	11	8	2
Shipbreaking	38	—	29	1
Electric accumulators	95	2	18	—

THURSDAY, MARCH 20TH.

The House went into Committee of Supply on the

Navy Estimates for 1924–25.

Dr. SPERO said the efficiency of the navy primarily depended upon the health of the Service. From the statement issued by the First Lord of the Admiralty one would imagine that all was well with the Naval Medical Service. He hardly made any reference at all to the Service except to say that the number of medical establishments had been reduced by two—namely, that the Yokohama Hospital was destroyed in the earthquake and the Royal Marine Infirmary was closed down owing to the transfer of the Royal Marine Division. Yet there was a shortage of medical officers in the Service, and at the present moment the Admiralty could not man all the ships with medical officers if they were sent to sea. This was a very serious position which called for immediate inquiry. At the end of January the shortage of medical officers was 39 below the complement required to maintain an efficient service. More men were retiring than entering the Service. The cause of the state of things was that the Admiralty had broken faith with their medical officers. As a result of the new regulations which came into force on Jan. 1st, 1920, medical officers who joined the Service under the distinct understanding that they would be retired at the age of 55, unless previously promoted, were compulsorily retired at the age of 50 without any compensation whatever. Moreover, the retirement was retrospective. The actual monetary loss to each medical officer in five years was £2200. The breach of faith affected junior as well as senior officers. He maintained that it was not from the medical officer's point of view a lucrative Service; in fact, it was a very precarious Service to enter and one that he quite agreed with the British Medical Association was not one which they could recommend young doctors to enter. The British Medical Association repeatedly brought the facts before the Admiralty, but the Admiralty seemed to think that there would be plenty of new candidates forthcoming when the output in the medical schools was at its height. But they had been very much disappointed. He would suggest one or two ways to induce young medical officers just leaving hospital to enter the Service. Remuneration must be the first consideration. A surgeon-lieutenant in the Royal Navy received £438 a year. A lieutenant joining the Royal Army Medical Corps got £555 a year. A married surgeon-lieutenant joining the R.A.M.C. got £617 a year, but a married officer joining the navy got only £438 a year. Perhaps the Admiralty believed in birth control; it looked like it. Again, supposing a medical officer was sent abroad—to China, for example. The Admiralty made no allowance to bring out his wife and family to him. Another reason why medical men would not join the Service was because of the want of opportunities for study. He suggested that the Admiralty should give more frequent opportunities for post-graduate study. There was such a scheme in connexion with the army. In the case of a court-martial the medical officer was the only officer on board who was not allowed to sit on the court even if one of his assistants was up for trial. The Naval Medical Officers' Department was on the top floor of an ordinary block of offices in Victoria-street. The Admiralty had made the medical service a thing apart, and as an old medical officer in the navy he felt that medical men on the whole were not being treated fairly.

Viscount CURZON said that Dr. Spero was perfectly right in saying that the shortage of medical officers in the navy was a very serious problem and it was one to which he (Lord Curzon) would ask the Admiralty to give their serious attention.

Mr. AMMON, Parliamentary Secretary to the Admiralty, replying to the debate, said that he gathered that Dr. Spero had spoken with the support of the medical profession generally as well as that of members of that profession in

the House of Commons. The hon. Member was probably not aware that a deputation from the British Medical Association had been received by the Admiralty on the point and the arguments of his speech were a recapitulation of the points put forward by the deputation. The whole matter was being gone into, and he hoped to reply to the deputation before long. But he ought to say this: The naval pay is £430 a year cash, while the army pay is less. The naval medical officer is also given lodgings and rations.

Lunacy Laws Inquiry.

Mr. ROBERT MORRISON asked the Prime Minister whether, when setting up the proposed body to inquire into the present lunacy laws and their administration, the terms of reference would be made wide enough to include an inquiry into the mental deficiency laws.—Mr. WHEATLEY replied: No, Sir, it is not proposed that the inquiry should extend to the mental deficiency laws. These form a separate and distinct subject-matter, the inclusion of which would, in my opinion, unduly delay the report and recommendations of the inquiry committee upon the more urgent question.

Overcrowded Maternity Wards in Hospitals.

Commander BELLAIRS asked the Minister of Health, in view of the prevalent overcrowding and the resulting increased need of maternity wards at hospitals, what assistance the Government would give in regard to capital expenditure and annual outlay so as to enable welfare centres, borough councils, and hospital committees to prepare schemes at once.—Mr. WHEATLEY replied: I am ready to give sympathetic consideration to proposals for the provision of maternity beds in areas where there is need for additional accommodation, and to pay grants not exceeding 50 per cent. of approved capital and annual maintenance expenditure. The grant in aid of capital expenditure usually takes the form of an annual payment based on the sum required for interest on and repayment of capital within a fixed period.

Medical Women on Lunacy Inquiry.

Mrs. WINTRINGHAM asked the Minister of Health whether, when appointing the committee of inquiry into the lunacy laws, he would include two women, one of the medical profession and one with special and practical knowledge of asylums visiting committees.—Mr. WHEATLEY replied: The hon. Member's suggestion will be carefully considered, but I cannot at present give any undertaking on this point.

Tubercle-infected Milk.

Sir HERBERT NIELD asked the Minister of Health whether he had received a series of resolutions with regard to the inadequate existing legislation with reference to tubercle-infected milk and the Milk and Dairies (Consolidation) Act, 1915; and whether he could see his way to put in operation without further delay the Tuberculosis Order of 1914, and also to introduce legislation to ensure the prevention of tubercle-infected milk being distributed and infected animals being slaughtered.—Mr. WHEATLEY replied: The answer to the first part of the question is "Yes." As regards the second part, I understand that my right hon. friend, the Minister for Agriculture, is considering the question of the reintroduction of the Tuberculosis Order. The hon. Member will be aware that the coming into operation of the Act of 1915 has been postponed by the Milk and Dairies (Amendment) Act of 1922 until Sept. 1st, 1925, and I do not think it will be practicable to introduce other legislation on this subject during the present session.

Dried Milk Regulations.

Mr. GILBERT asked the Minister of Health whether, as the final conference between the Health Department and the representatives of the dried milk trade only took place on Jan. 24th last, and in view of the time required for printing the large stocks of tins, &c., required to comply with the Order, he would postpone the date, May 1st, for the operation of the Public Health (Dried Milk) Regulations to enable the trade to clear the market of outstanding stock and so avoid the unnecessarily heavy loss that would otherwise be incurred.—Mr. WHEATLEY replied: The Public Health (Dried Milk) Regulations were made on Nov. 5th, 1923, to come into operation on May 1st, 1924. The regulations were published in draft on July 24th, 1923, and the representations of the trade were considered, and met, as far as possible, before the regulations were made. I am satisfied that the trade had ample notice of the provisions of the regulations and I see no reason for postponing their operation.

Tubercle-infected Cattle.

Mr. BARNES asked the Minister of Agriculture whether he had received representations from local authorities urging the necessity for legislation to eliminate tubercle-infected cattle from the dairy herds in this country in the interests of public health; and whether he could hold out any promise of early legislation.—Mr. SMITH replied: The answer to the first part is in the affirmative. The matter is being carefully and sympathetically explored, but I am not yet in a position to make any statement on the subject.

MONDAY, MARCH 24TH.

Vaccination Act.

Mr. BLACK asked the Minister of Health the cost of administering the Vaccination Act, 1907, in Great Britain for the last year with respect to the remuneration of vaccination officers; the cost of providing the exemption certificate forms, and any other expenses involved; and how much of the cost fell upon the taxpayer and how much upon the ratepayer.—Mr. WHEATLEY replied: It is not possible to state separately the expenditure incurred on the remuneration of vaccination officers. The total expenditure of boards of guardians on public vaccination for the year ending March 31st, 1922 (the last year for which complete figures are available), was £162,400, the whole of which was defrayed out of local rates. During the same year the sum paid to public vaccinators out of the Exchequer contribution accounts of the local authorities amounted to £10,200, while the approximate cost to the Exchequer of vaccine lymph supplied to public vaccinators and medical officers of health was £11,800. The cost of printing the new form of declaration of conscientious objection has been £67 up to date.

Prison Discipline.

Mr. HAYES asked the Home Secretary whether, in view of the fact that at Parkhurst Prison the medical officers and the registered nurses were experienced in prison discipline, the question would be considered of ceasing to furnish them with truncheons and handcuffs; and why the hospital principal was not relieved by a member of the hospital staff instead of by a discipline principal.—Mr. HENDERSON replied: The hospital officers, like other officers at Parkhurst, carry staves as a part of their ordinary equipment. They have never been used, and the necessity for requiring the officers to wear them when within the hospital is being considered by the Prison Commissioners. Handcuffs are only used for purposes of escort to another prison. The hospital principal officer is relieved by a discipline principal officer pending the transfer of another hospital principal officer from another prison.

Panel Practitioners' Fees.

Sir KINGSLEY WOOD asked the Minister of Health whether he was now in a position to make a statement relating to his proposals concerning the payment of medical men on the panel lists.—Mr. GREENWOOD, Under Secretary to the Ministry of Health, replied: The Government proposals in regard to the matter referred to by the hon. Member are embodied in a Bill which is being introduced to-day.

National Health Insurance Bill.

Later Mr. WHEATLEY introduced the National Health Insurance (Cost of Medical Benefit) Bill, the object of which is "to make further provision with respect to the cost of medical benefit and to the expenses of the administration of benefits under the Acts relating to National Health Insurance, and to amend Section 29 of the National Health Insurance Act, 1918; and for purposes connected therewith." The Bill was read a first time.

Consumption Among Convicts.

Mr. SOMERVILLE HASTINGS asked the Home Secretary whether he could state the percentage of convicts, male and female, who had developed pulmonary consumption during the last five years.—Mr. RHYS DAVIES, Parliamentary Secretary to the Home Office, replied: There were only four cases of pulmonary consumption among male convicts, giving a percentage of 0·16 of the total receptions for the past five years. There were no cases among female convicts.

R.A.M.C. Lieutenants.

Lieut.-Colonel POWNALL asked the Secretary of State for War what was the number of lieutenants in the Royal Army Medical Corps and what was the normal establishment for this rank.—Major ATTLEE replied: The number of lieutenants in the Royal Army Medical Corps is 14, of whom three are seconded. There is no fixed establishment for this rank.

During the debate on the Army Estimates, Lieut.-Colonel POWNALL said that the R.A.M.C. had practically stopped getting fresh recruits of officer rank. The February army list showed seven lieutenants in the whole of the corps, and the majority of these were on probation. In view of the fact that the establishment was some hundreds, there was obviously something very much at fault with the methods of recruiting. He asked the War Office what steps were being taken to secure a reasonable supply of young officers for the corps. The whole health of the army was involved and the question was a most serious one. Unless recruits were forthcoming they would soon find themselves with a corps consisting only of majors and lieut.-colonels.

TUESDAY, MARCH 25TH.

Nil Disability.

Mr. HUTCHISON asked the Minister of Pensions if his attention had been drawn to what was termed "nil disability"; whether he was aware that, when the man's panel doctor certified the man to be suffering from disability, if the medical board decided "nil disability" no right of appeal was allowed against that decision; and would he take steps to allow the right of appeal.—Mr. J. W. MUIR replied: I am not quite clear what class of case the hon. Member has in mind. In cases where the medical board find that there is no appreciable degree of disablement, the award given is one of "nil disablement," and the man concerned has a right of appeal thereon to the assessment appeal tribunal or to a medical appeal board, according as the award is or is not declared a final award. Exceptionally a case has occurred in which the medical board are wholly unable to discover that the claimant has the disability or ailment claimed at all. Where such cases have arisen it has been arranged that the man's appeal should go forward if he desires to appeal. General instructions are being issued.

The Schick Test.

Mr. BROMFIELD asked the Minister of Health what was the composition of the diphtheria toxin which was used for carrying out the Schick test; and how supplies of it were obtained.—Mr. WHEATLEY replied: The test solution in the Schick test for diphtheria consists of a fresh solution of diphtheria toxin which is bacterium-free and is prepared and diluted so that either 0·1 c.cm. or 0·2 c.cm. (as may be decided) represents one-fiftieth of the minimum lethal dose for a 250 g. guinea-pig. Supplies of diphtheria toxin used for this purpose in this country are obtained from the two or three commercial firms which have made special arrangements for its preparation and sale.

Mr. SUNLIGHT asked the Minister of Health whether his attention had been drawn to the recent serious results of inoculating children with toxin-antitoxin in certain educational establishments in two towns in the United States, damages having been recently awarded for the death of a child through inoculation with toxin-antitoxin; and whether, in view of these and other records of disasters in America through the use of the Schick test and subsequent inoculation with toxin-antitoxin, he would dissociate his department from a system which might cause severe injury and even death to those submitted to it.—Mr. WHEATLEY replied: The answer to the first part of the question is in the affirmative, except that I have no information as to any death resulting from the inoculations referred to. I understand that the reactions following the inoculation of these children were due to their receiving a toxin-antitoxin mixture which had been subjected to extreme cold, this causing a dissociation of the mixture. Now that the unfavourable effect of freezing the mixture has been ascertained, suitable precautions will, of course, be taken in future, and I see no reason to modify the advice given in the reports issued by my department on the use of immunisation methods against diphtheria.

Panel Practitioners.

Mr. TURNER asked the Minister of Health if he would state the number of medical practitioners on the National Health Insurance panel in England and Wales; and what was the average number of panel patients to each medical practitioner on the panel in the West Riding of Yorkshire.—Mr. WHEATLEY replied: The average number of insurance practitioners for England and Wales for the year 1923 was approximately 12,850. The average number of panel patients to each insurance practitioner for the West Riding of Yorkshire was for the same year approximately 1100.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, Piccadilly, W.

THURSDAY, April 3rd.—4.30 P.M., *Papers to be read:* Sir Charles Sherrington, P.R.S., and E. G. T. Liddell: Reflexes in Response to Stretch (Myotatic Reflexes). H. M. Carleton and G. C. Robson: The Histology and Function of Certain Sex-limited Characters in the Cuttle Fish *Doratosepion confusa*. (Communicated by Sir Charles Sherrington.) *Paper to be read in Title only:* Dr. J. G. Dusser de Barenne: Experimental Researches on Sensory Localisation in the Cerebral Cortex of the Monkey (Macacus). (Communicated by Sir Charles Sherrington.)

MEETINGS OF SECTIONS.

Monday, March 31st.

Social Evening.

Fellows, Members of Sections, Associates, and their friends, will be received by the President, Sir William Hale-White, and Lady Hale-White, at 8.30 P.M.

Sir John Goodwin (late Director-General A.M.S.) will give, at 9 P.M., a brief discourse entitled "Reminiscences."

Music, light refreshments and smoking.

Tuesday, April 1st.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Discussion:

On the Treatment and Functional Results of Tuberculous Disease of the Hip-joint, to be opened by Dr. Gordon Pugh and Mr. T. P. McMurray.

The Discussion will be continued by Mr. Elmslie (President), Sir Henry Gauvain, Mr. Fairbank, Mr. Acton Davis, and others.

Wednesday, April 2nd.

SURGERY: at 5.30 P.M. (Cases at 4.30 P.M.)

Clinical and Pathological Meeting.

Thursday, April 3rd.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Prof. Louise McIlroy: An Apparatus for Measuring the New-born Infant.

Short Communications:

Dr. Gilbert Strachan: Combined Carcinoma and Tuberculosis in the Uterus.

Dr. Everard Williams: A Case of Acute Pemphigus in Mother and Child.

Paper:

Dr. Remington Hobbs: The Causes of Acute Infection of the Uterus, including Puerperal Sepsis and Septic Abortion, and their Treatment by Drainage.

Friday, April 4th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)

Cases and Specimens will be shown by Mr. W. M. Mollison, Mr. Jefferson Faulder, Mr. M. Vlasto, Sir James Dundas-Grant, Mr. H. M. Wharry, Mr. F. C. Ormerod, Dr. J. Aldington Gibb, Mr. H. J. Banks-Davis, Mr. J. F. O'Malley, Mr. Norman Patterson, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, April 1st.—5 P.M., Dr. Leonard G. Parsons: Wasting Disorders of Early Infancy. (Last Goulstonian Lecture.)

THURSDAY.—5 P.M., Dr. Thomas McCrae: Clinical Features of Foreign Bodies in the Bronchi. (First Lumleian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

MONDAY, March 31st, to SATURDAY, April 5th.—BETHLEM ROYAL HOSPITAL. Course in Psychological Medicine. Tues., 11 A.M., Dr. Thomas Beaton: The Psychoses. Sat., 11 A.M., Dr. Porter Phillips: The Medico-Legal Aspect of Insanity.—LONDON TEMPERANCE HOSPITAL, in conjunction with BETHLEM ROYAL HOSPITAL, NORTH-WESTERN FEVER HOSPITAL, and the ROYAL WESTMINSTER OPHTHALMIC HOSPITAL. Special Intensive Course (first week).—ROYAL FREE HOSPITAL. Wed., 5.30 P.M., Dr. Heald: Diagnosis and the Selection of Electrical Treatments.—ROYAL WATERLOO HOSPITAL. Lecture Demonstrations, Ward Work, &c. Mon., 2 P.M., Dr. Woodwark; 3 P.M., Dr. Barron. Tues., 2 P.M., Dr. Myers; 4 P.M., Dr. M. Davidson. Wed., 1.30 P.M., Mr. Cairns Forsyth. Thurs., 1.30 P.M., Dr. R. J. Perkins; 2.30 P.M., Mr. Bickerton; 3.30 P.M., Dr. Myers. Fri., 2 P.M., Dr. R. J. Perkins and Dr. Donaldson; 4 P.M., Mr. Beevor. Sat., 9.30 A.M., Mr. Frankau (Operations). Further particulars can be obtained from the office at 1, Wimpole-street, W.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, March 31st.—10 A.M., Surgical Registrar: Surgical Pathology. 12 noon, Mr. Sinclair: Surgical Diseases of the Abdomen. 2 P.M., Mr. Bishop Harman: Eye Department.

TUESDAY.—11 A.M., Dr. McDougal: Electrical Department. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—12.15 P.M., Dr. Buruford: Medical Pathology. 2 P.M., Dr. Pernet: Skin Department. 2.30 P.M., Mr. Armour: Surgical Wards.

THURSDAY.—11 A.M., Mr. Simson: Gynæcological Demonstration. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Department.

FRIDAY, 10.30 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Department.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily 10 A.M., to 6 P.M., Saturdays, 10 A.M., to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Prince of Wales's General Hospital).

At 4.30 P.M.

MONDAY, March 31st.—Mr. Aubrey Goodwin: Vaginal Discharge.

TUESDAY, April 1st.—Mr. C. H. Hayton: Treatment of Atrophic Rhinitis with Ozena (with cases).

WEDNESDAY.—Dr. J. Browning Alexander: Bronchiectasis.

FRIDAY.—Dr. C. E. Sundell: Dyspepsia of Infancy.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 4th.—4 P.M., Mr. Gill-Carey: Chronic Suppurative Otitis Media.

HOSPITAL FOR SICK CHILDREN, Great Ormond-st., W.C.

THURSDAY, April 3rd.—4 P.M., Dr. Thompson: Intracranial Tumours.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

THURSDAY, April 3rd.—5 P.M., Mr. Banister: The Treatment of Contracted Pelvis.

VICTORIA UNIVERSITY OF MANCHESTER MEDICAL SCHOOL.

FRIDAY, April 4th.—5.30 P.M., Dr. G. Northcroft: The Teeth in Relation to Normal and Abnormal Growth.

MANCHESTER CLINICAL SOCIETY.

THURSDAY, April 3rd.—4.30 P.M. (at the University), Dr. Sequeira: Recent Work in Treatment of Disease by Artificial Light.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE LECTURES.

TUESDAY, April 1st.—4.15 P.M., Dr. W. Fletcher Shaw: Leucorrhœa.

Appointments.

FAIRWEATHER, J. W. C., M.B., Ch.B. Edin., has been appointed Medical Officer and Vaccinator for the Parish of Fordoun.

PATTISON, C. LEE, M.B., B.S. Lond., L.R.C.P. Lond., M.R.C.S., Consulting Surgeon to the Tuberculosis Department of the Rotherham Corporation.

Salford Royal Hospital: KNOX, J. F., M.B., Ch.B., B.A.O. Belf., Resident Medical Officer; REID, S. I. H., M.B., Ch.B., B.A.O. Belf., House Physician; TALBOT, G., M.B., Ch.B., B.Sc. Manch., and MCCLURE, C. R., M.R.C.S., L.R.C.P. Lond., House Surgeons: and CRAIG, J. C. B., M.B., Ch.B. Edin., Casualty House Surgeon.

Surgeons under the Factory and Workshop Acts: BRYSON, M., M.B., C.M. Glasg. (Thornhill); SALMON, N. G. H., M.B., B.S. Lond. (Bodmin); BUTLER, T. L., L.R.C.P. Lond., M.R.C.S. (Sherston).

Vacancies.

For further information refer to the advertisement columns.

Birmingham, St. Chad's Hospital.—Res. M.O. £100.
Birmingham Union, Selly Oak Hospital.—Res. Asst. M.O. £300.
British Guiana Diamond Fields.—Government M.O. £500.
Cancer Hospital, Fulham-road, S.W.—H.S. £100.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Radiographer.
Charing Cross Hospital, W.C.—Med. Reg. and Surg. Reg. Each £150. Also Asst. Surg.
Derbyshire Royal Infirmary, Derby.—H.S., &c. Also Asst. H.S., &c. Each £200.
Dublin University, Trinity College.—Prof. of Pathology. £800.
Evelina Hospital for Children, Southwark, S.E.—H.S. and H.P. Each £160.
Hospital for Consumption and Diseases of the Chest, S.W.—H.P.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S., H.P., and Asst. Cas. O. £50.
Hull City Asylum.—Med. Supt. £1000.
Keighley, Victoria Hospital.—H.S. £180.
Kensington, Fulham, and Chelsea Hospital, Richmond-road, Earl's Court, S.W.—Sen. and Jun. Res. M.O.'s. £100 and £75 respectively.
King's College Hospital, Denmark Hill, S.E.—Jun. P.
Lambeth Parish Hospital.—Jun. A.M.O. £200.
Leeds City.—Chief Clin. Tub. O. £900.
London Jewish Hospital, Stepney Green, E.—Cas. O. £200.
London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. and Med. Reg. Each 10 guineas.
Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Res. M.O. £125.
Manchester, Baguley Sanatorium.—Third Asst. M.O. £400.
Metropolitan Hospital, Kingsland-road, E.—Sen. H.P., H.S., Jun. H.P., H.S., and Two Cas. O.'s. Each £100. Hon. Anæsthetist.
Norfolk County Council.—Asst. Tub. O. £600.
Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £150.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. S.
Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.
Poplar Metropolitan Borough.—Asst. Tub. O. £600.
Prince of Wales's General Hospital, Tottenham, N.—H.S. H.P. Each £150. Jun. H.S. and Jun. H.P. Each £110.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—R.M.O. £200.
Rangoon Corporation.—Health Officer. Rs.1200 per month.
St. John's Hospital for Diseases of the Skin, Leicester-square, W.C.—Clin. Assts.
Sheffield Royal Hospital.—Asst. Cas. O. £100.
Somerset Mental Hospital, Wells.—Asst. M.O. £300.
Stafford, Coton Hill Mental Hospital.—Med. Supt. £600.
Surrey County Council.—Asst. M.O.H. £600.
Tunbridge Wells General Hospital.—H.S. £160.
West London Hospital, Hammersmith-road, W.—Hon. Med. Reg.
Western Australia, Medical and Health Dept.—Bacteriologist and Pathologist. £708.
York County Hospital.—H.P. £150.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Milborne Port, Somerset; Northwich, Cheshire; Dronfield, Derbyshire.

Births, Marriages, and Deaths.

BIRTHS.

CLARKE.—On March 19th, at Victoria-square, Clifton, Bristol, the wife of Dr. Richard C. Clarke, of twin daughters.

ELLISON.—On March 25th, at 36, Devonshire-place, W. 1, to Dorothy, wife of John Ellison, a daughter.

HODGSON.—On March 16th, at Andover, the wife of Dr R. G. K. Hodgson, of a son.

OSBORN.—On March 17th, at Sheet-street, Windsor, the wife of Dr. A. G. Osborn, of a daughter.

MARRIAGES.

MORRISON—MARSDEN.—On March 25th, at Sefton Park Presbyterian Church, Liverpool, by the Rev. George H. Morrison, D.D., of Wellington Church, Glasgow, father of the bridegroom, assisted by the Rev. J. Somerled Macdonald, M.A., George Herbert Morrison, M.B., Ch.B., to Helen Mary (May), elder daughter of Mr. and Mrs. J. Wilberforce Marsden, 26, Croxteth-road, Liverpool, and grand-daughter of the late Rev. Henry Marder Douglas, of Kirkcaldy.

DEATHS.

MACEWEN.—On March 22nd, at Woodside-crescent, Glasgow, Sir William Macewen.

REID.—On March 22nd, at St. Augustine's-mansions, S.W., Douglas Arthur Reid, M.D., J.P., in his ninety-first year, assistant surgeon 90th Light Infantry during Crimean War.

RUNDLE.—On March 19th, at Clarence-parade, Southsea, Henry Rundle, F.R.C.S., aged 79.

SYDENHAM.—On March 18th, George Francis Sydenham, F.R.C.S., J.P., of Dulverton, Somerset, aged 63 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

CYTOCLESIS.*

A PHENOMENON EXPLAINING THE COURSE OF EMBRYONAL DEVELOPMENT.

By F. Wood Jones, D.Sc. Lond., M.R.C.S. Eng.,
Professor of Anatomy, University of Adelaide.

It was in 1913, at the International Congress of Medicine held in London, that Ariens Kappers, of Amsterdam, first succeeded in making the bulk of British anatomists appreciate his conception of "neurobiotaxis." That an animal reacts to a sensory stimulus by an appropriate motor response is a phenomenon familiar to everyone. That a newborn animal will do this is common knowledge. Directly the nipple of the mother is near to the newborn pup's nose the sightless senseless creature grasps it with its lips, and the whole complex mechanism of suckling is initiated. The contrivance by which the sensory stimulus of the contact with the nipple produces the appropriate motor response of the movements of the lips and tongue in suckling is laid down in the central nervous system of the pup long before it is born.

The underlying principle of this contrivance was first defined by Ariens Kappers. Suppose that sensory impulses are streaming in, or will one day stream in, from some sense organ to a sensory nerve centre in the brain; in order to fulfil the whole rôle of life, sensation must be acted on and movement must be produced. The sensory nerve centres must, therefore, be related not only in some way to motor nerve centres, but to the *appropriate* motor nerve centres; the embryological bases of the mechanisms of the future in-streaming sensory impulses always "call" to their nerve centres the motor nerve centres which are so linked up with the motor nerves and muscles as to produce the most appropriate reflex response. In the developing brain these things are called together; the living, developing, sensory nerve cells call the living motor nerve cells and hold them by some strange force, remaining in apposition whilst all else around them changes.

Here is something more subtle even than a hormone: a call of cell to cell, a hold of cell on cell; a call exerted long before function demands the harmonious outcome of the call; a call of predestiny; a call of ancestral memory—it matters not what it is termed. In the arrangement of the embryonic sensory and motor ganglia in the brain stem we are dealing with well ascertained facts; no work previous to that of Ariens Kappers and Davidson Black afforded any sort of solution to the problem of the varied arrangement of these ganglia in the different types of animals. Neurobiotaxis is a term applied to the peculiar "call" evinced among the myriad cells which constitute the central nervous system; but the call is not limited to the central nervous system. There is a general phenomenon of cell call, a wonderful influence which living cells exert, and this strange force I shall here name cytoclesis, for which term I am indebted to Prof. Darnley Naylor.

Cytoclesis in the Development of the Eye.

Some of the most beautiful manifestations of cytoclesis are unfolded in the relation of the nervous system to other systems and organs in the body. Take, for example, the eye and its appendages. As the rudiment of the developing eye grows towards the skin there come into being, at the site of its coming, the rudiments of the superficial parts of the organ of vision. From first to last the story of the developing eye moves in a fairyland of insoluble mysteries. First tucked away (and, one would hazard, folded in by an ill-chance) within the dark neural tube, the eye struggles to regain the surface of the head, which one day will be exposed to the rays of light. After its probation period as part of the infolded neural tube, after its painful struggles to be free and to grow towards the surface, where in the distant future it will meet those rays which alone can set its cells vibrating, it still has its trump card to play; it still has its call. Something called it to the surface, and as it approaches the surface its own call goes forth, and the cells of the embryonic skin of the surface of the face respond to the call. The optic cup, growing outwards from the brain, will form the light-sensitive parts of the eye hidden in the layers of the retina; but these parts were useless if the optic cup remains covered by the ordinary opaque skin. It therefore calls to the ectoderm cells of the area towards which it is growing, and a transparent lens and cornea are called into being from cells which elsewhere form the ordinary opaque skin. That the changes which result in the formation of the lens are due to cytoclesis exerted by the optic cup seems beyond question. Should the optic cup fail to develop, or should it fail to grow towards the surface, then the call does not reach the ectoderm of that portion of the face where the transparent media of the eye should be developed, and lens formation does not take place. Moreover, the astonishing work of Lewis (1904) and Sphemann (1912) has shown that if the developing optic cup of a tadpole be removed from its original site and transplanted beneath the embryonic skin of some other part of the body it can still exert its cytoclesis and produce a lens in an altogether abnormal situation. The call is lodged in the cells of the optic cup, and this call may be responded to by the skin of the abdomen if the optic cup be transplanted there. That the embryonic skin of the abdomen should be able to form a lens for a transplanted portion of an eye is a marvel, and only one force, the cytoclesis of the optic cup, can produce the marvel.

Cytoclesis in the Development of the Alimentary System.

Ignoring a host of other instances in which cytoclesis is dramatically displayed in the developing nervous system and its accompanying sense organs, it is well to pass to other systems of the body to see new manifestations of the process. In the developing alimentary system the influence of cytoclesis is seen everywhere. The relation of the stomodeum and the foregut, the call of the liver cells to the vitelline blood, manifest the same phenomenon. But for a grand display we may turn to the developing hind gut and the skin of the perineal region. When the hollow tube, derived from the hypoderm, which constitutes the hind gut or large intestine, grows backwards towards the hind end of the body it exerts its call upon the ectodermal skin of the hind end, and the ectodermal cells start to grow inwards to meet the advancing tube. A skin dimple is thus produced; a skin ingrowth is formed to meet the intestinal downgrowth, a rectum approaches a preformed anus. As the rectum approaches the anal dimple deepens; they are guided towards each other so that they come in contact and only a septum separates them. The septum breaks down, and the alimentary tube opens by an orifice on the surface of the skin. The hypoderm cells of the hind gut have exerted their cytoclesis upon the ectoderm cells of the perineum. But if the rectal downgrowth fails to develop in a normal manner, if that portion which I have termed the "post-allantoic gut" is not perfected, then no call is felt by the ectoderm of the hind end, and the anal dimple fails to develop. Here we almost seem to have a space limit for the action of cytoclesis. A complete failure of the development of the post-allantoic gut results in a complete absence of the call to the ectoderm, and no anal ingrowth is formed. In this way there results the condition of imperforate rectum. But any degree of development of the post-allantoic gut exerts its cytoclesis, feeble or powerful, and some formation of an anal ingrowth takes place. In this way there result the varying degrees of imperforate anus. The cytoclesis of the hypodermic hind gut appears to be exerted on the ectodermic cells of the perineal region only when the hind gut has developed so far as to form a "post-allantoic" portion.

Cytoclesis in the Renal Excretory Apparatus.

I turn now to the manifestation of the cell call in the formation of the renal excretory apparatus. The myriad secreting tubules of the kidney are formed in the hind portion of the great secreting primordium known as the Wolffian body. The myriad minute collecting ducts are formed from an altogether different embryological basis, for they are budded out from the main kidney duct or ureter. Nevertheless, although these two entities are involved in the completion of all the kidney tubules, there is the marvel that results in each secretory tubule in the metanephric portion of the Wolffian body meeting a collecting tubule from the ureter accurately end to end. From the glomerulus, where urine is separated from blood, to the ureter, by which urine is conveyed to the bladder, there is a complete duct; a myriad of such complete ducts. But each duct is composed of two sections, preformed from different embryological elements, but guided to meet each other by a call; each kidney tubule meets each ureteric tubule end to end, and so completes the canal. Here is wholesale cytoclesis: thousands of tubules in each kidney meeting end to end, as the cut ends of thread in two tangled skeins might find each other and join. Again, cytoclesis may fail, and then the myriad secreting tubules of the kidney fail to open into the myriad collecting tubules of the ureter. In this condition the secretory metanephric tubules, having no outlet, dilate with their own secretion into the curious pathological manifestation known as congenital cystic kidney. Congenital cystic kidney is an evidence of the failure of the cytoclesis of the metanephric tubules.

There is no need to multiply instances. Of a certainty cytoclesis is everywhere displayed in the tissues of the animal

* An abstract of part of the commemoration address on "The Position of Anatomy in the Modern Medical Curriculum," delivered in 1923 at the University of Adelaide.

body. Surely it is not too imaginative a thesis to maintain that this ordered call of cell to cell, this prompting as to station, is in reality *the* force which determines that a definite ordered system of organs is created out of a cellular mass. The whole completed perfection of the animal body is in itself evidence of the action of cytoclesis. We are the products of cytoclesis. A community of cells in some way conducts its own destiny, so that by the cytocletic word of command some cells take their station here and some there. An embryo may be said to be a cell community governed and directed by cytoclesis. It is remarkable that long before the microscope was introduced into anatomical studies, and still longer before the cellular nature of tissues was demonstrated, the conception of the animal body as a microcosmos was in general acceptance. In 1651, when Helkiah Crooke wrote his highly instructive work on human anatomy, he entitled it "Microcosmographia: a Description of the Body of Man." So much modern work has progressed upon purely physical or chemical lines of research that we are, maybe, in some danger of regarding the body as a test tube in which chemical reactions occur, or as a thing of which the whole ordered building is a mere matter of simple physical laws.

There are, indeed, some signs and portents that certain of the more subtle chemical explanations of vital phenomena need further examination. The recent work of Cramer seems to indicate that the most elusive of chemical agencies, that of the vitamins, resolves itself into the familiar story of structure and function, rather than one of undefinable chemical action. Deprivation of a vitamin appears to damage a cell complex, and owing to the damage of a series of cells the whole tissues suffer. The ailing of the body in consequence of the damage of a tissue or cell community is a concept different from that of a body suffering from the deprivation of an obscure chemical factor, but altogether in harmony with the picture of the cellular microcosmos ordered by cytocletic action.

Processes of Formation and Repair: A Comparison.

In many ways the formation of parts in the developing embryo is singularly like the process which accompanies the repair of damage inflicted in adult life. The further we go back along the animal scale the more alike the processes become. The power of repair of the human body is limited; we cannot vie with those animals which can renew a limb after its complete loss; nevertheless, the wonders of the possibility of repair in human tissues are manifold. For instance, no surgeon can so accurately oppose the two cut ends of a divided nerve that each regenerating fibre may be opposite its dead and degenerating continuation: and, indeed, one end of the divided nerve may be given a half turn and united thus, and still, when healing is complete, function will be restored. Now, in an ordinary mixed nerve there are sensory fibres and motor fibres, each having its proper connexion in the spinal cord, each having its proper terminal in skin or muscle. It is marvel enough that the down-growing fibres should even find the tubular sheaths of the degenerated portion; it is marvel beyond comprehension that the motor fibres, growing from cells in the anterior horn of the spinal cord, should follow the old sheathing that leads to end-organs in muscles, while the sensory fibres, growing from cells in the posterior root ganglia, find that which leads to the end-organs in the skin. Cytoclesis guides the regenerating fibre along the proper pathway that leads to its appropriate end-organ. And in the repair of bone, or the alteration of bone structure with the development of new strains and stresses, in the processes of healing as displayed in any tissue, everywhere in the details of repair the hand of cytoclesis is to be seen. If cytoclesis be the process which leads to the ordered formation of parts and organs, it surely is the process which leads to their ordered reformation after injury.

If there is a fault to be found with modern medicine, and especially with modern surgery, it might be urged that sufficient regard is not always paid to the wonderful powers of the vis medicatrix naturæ. The more conquests we have, the more successful we become in treating bodily ills, the less we are inclined to ascribe to the vis medicatrix naturæ the cure of our "cases." There is a desire often manifested by the surgeon, and to a lesser degree by the physician, to cure the patient, rather than to put him in the way of deriving the benefit of the cytocletic action of repair. It is a mercy that modern medicine, which has jurisdiction over our methods of repair, has no jurisdiction over our methods of formation. Few surgeons would care to permit the kidney to develop in its extremely risky manner; of a surety they would do an operation to ensure an end-to-end junction of the tubules.

Cytoclesis and Malignancy.

Cytoclesis, we may believe, is the factor of ordered formation and ordered reformation. But perhaps it has another and a more sinister rôle. In many processes of normal embryonic growth there is presented a picture of what may be termed the invasion of one tissue by another. Cytoclesis appears to be able to call from tissue to tissue, so that the cells of one tissue invade an intervening tissue in order to reach their goal. The curious cells of the embryonic trophoblast have one call, one function; through the maternal uterine tissue they seek the blood-vessels from which the embryonic nourishment may be obtained. In the cells of the trophoblast cytoclesis may be said to manifest itself as a blood quest; a blood quest which causes these cells to invade the uterine mucosa in a manner which, without being fanciful, we may describe as hostile. There is something strange in the behaviour of these syncytial cells, something even in their normal behaviour which suggests that type of tissue hostility which we term malignancy. The blood quest of the trophoblast is normally hostile in the maternal tissues; abnormally we know too well it may become in fact malignant, malignant with the terrible malignancy of deciduoma malignum. Again, the growth of the liver cells towards the vitelline blood has much in it to suggest a cytocletic hostility, a call which is answered regardless of intervening tissues. Is it possible that, in the adult, a perversion of cytoclesis or an untimely reawakening of cytoclesis produces the phenomenon of malignancy? Such a conception would seem to fit in with most of the known facts. Give the anatomist cytoclesis and he holds the key of admittance to hospital wards, operating theatre, and clinics. In all these spheres he has a rightful place, and if modern medicine and modern surgery do not admit him to their councils the loss is theirs, or rather that of their patients.

SMOULDERING CLOTHES.

To the Editor of THE LANCET.

SIR,—I had this week the misfortune to be present at a grave burning accident to a girl of 12 years and was greatly impressed by three things: (1) that although flame is easily extinguished by coats and rugs, smouldering is very difficult to extinguish, especially in the less accessible regions; (2) that clothing even under the best circumstances cannot be removed with desirable speed: (3) and last of all, with the great difficulty I had in persuading the bystanders to bring me water for extinguishing purposes. I found the cause for this later in two popular text-books of first-aid where the use of water in extinguishing burning clothing is not mentioned, I presume, because of the mess caused by the carbonised material when wet. Could any of your readers enlighten me as to the reason for this? A horrifying amount of avoidable suffering could be prevented if this superstition were eradicated. I cannot understand what harm can be done by lukewarm water.—I am, Sir, yours faithfully,

March 17th, 1924. "HUMANITY."

ABDOMINAL CONTROL.

A FIRST-CLASS athlete, who, as years advanced, began to run to fat, has written a little book[1] to tell us how he reduced his own weight, and how he does the same for others. Part I. consists of 11 short chapters. The author states his own story, and gives a brief epitome of Sir Arbuthnot Lane's condemnation of the faulty colon. He deals with posture and its value, and with enteroptosis and its disadvantages. In the chapter devoted to flat feet, he says truly enough: "The grace of movement is destroyed, while headache, backache, and general weariness help to complete the misery of the subject." The value of exercise after operation and confinement is well set out. He points out the danger of the muscular wall of the abdomen losing "tone" permanently, and, with true optimism, adds that the "early and judicious employment [of massage] after operation is now a recognised measure all over the civilised world." He says of the time-honoured binder used in post-maternity work, and with much truth: "It certainly gives .... a feeling of comfort .... but, so far as helping to restore the muscles to their normal state, the binder might as well have been tied round the bedstead." The author's views on golf as exercise are interesting. The two chapters on abdominal control are plain common-sense; and when speaking of diet, importance of the fluid intake is emphasised. The chapter which deals with faults of the usual systems of exercise is severe. Doubtless they are true if the "system" is picked up casually or is improperly taught, but the general condemnation is rather too sweeping.

Part II. consists of a description of eight exercises which should be used by the obese for the reduction of weight. These are to some extent familiar. For example, the heels-raising-knee-bending exercise. Others are newer and should be of service. The descriptions are good, and photographs, with the exception of No. 6, the indications of which are not very clear, make it easy to follow the meaning of the text. The book is worthy of attention, and the application of the principles set out ought to meet with success.

MEDICAL RECIPROCITY IN UKRAINE.

To the Editor of THE LANCET.

SIR,—May I ask the hospitality of your columns to invite British medical men who know the Ukrainian language and are interested in the progress of medical and surgical science in the Ukraine to communicate with the Ukrainian Red Cross Society, 150, Southampton-row, London, W.C. 1. It is desired to offer medical journals and other papers for exchange and in other ways to endeavour to maintain contact between the medical faculties of the two countries. Ukrainian doctors would be glad to learn of their British colleagues and may have something of interest to offer in return. I am, Sir, yours faithfully,

March 21st, 1924. ALEXANDRA RACOVSKI.

"AMBIDEX" NAIL BRUSHES.

THESE are cheap but efficient bristle brushes, stiff enough to cleanse the nails yet sufficiently soft to be used with comfort for the hands. In order to avoid the use of the finest bristle, which is expensive, the Barnett Brush Manufacturing Co., Ltd., Sandringham Works, Enfield Highway, Middlesex, employ a special method of cutting bristles with a very satisfactory result. The backs of the brushes are so constructed that a firm grip by the fingers can be maintained, while the hollow shape of the face of the brush makes it possible to reach all parts of the hand. At the same time the brush wears evenly and does not go flat in the middle. The prices vary from 1*s.* 6*d.* to 7*s.* 6*d.*, according to the quality of the bristles used and the size of the brush.

AMBULANCE CAMELS.

OVER a century ago the camel was employed by European armies in the East for the transport of casualties, but since then the rôle of that patient beast of burden in military medical history has been somewhat intermittent. Writing in a recent issue of the *Journal of the Royal Army Corps*, Capt. E. B. Marsh records that Napoleon used camels in Egypt for carrying the sick and wounded, who were slung in pairs, one on each side of the camel, in litters devised by Baron Larrey. He reminds us, too, that Surgeon-Major F. H. Brett, surgeon to the Governor-General's bodyguard, recommended, in 1839, such camel transport as "the most comfortable and safe mode of invalid travelling that I have ever heard or read of." But a thoroughly satisfactory litter or "Kajawah" had not been found, so ambulance camels ceased to be employed. There were a few still in Afghanistan in 1879, but in the Malakand in 1897 and in 1905 no mention is made of them. The late war, however, saw camels again mobilised in Egypt, in Mesopotamia, and in East Africa, but they came into their own in Waziristan in 1919–20, when some 90 per cent. of the wounded were thus evacuated. The camel's large, padded feet made it particularly suitable for work in the stony ravines and fords of that area. While it took eight orderlies to carry a man on a stretcher, one orderly could look after four patients on two camels. The kneeling and rising of a camel gives a nasty jerk to his burden, but at large stations, like Jandola, embarking and disembarking platforms were built. One camel will carry from 400 to 600 lb., but he will only march 2½ miles an hour.

A BIBLIOGRAPHY OF EUGENICS.

THE information we possess on the biological evolution of man is so widely scattered that a Bibliography of Eugenics[1] will be welcomed. The net has been cast wide, perhaps too wide, and a good deal of rubbish is sandwiched between contributions of recognised value. Prof. Holmes acknowledges that the literature on this vast subject is very much at loose ends; much of it is uncritical; and comparatively little of it is written with the competence of the highly trained specialist.

The sections into which the mass of inchoate material is divided are as follows: Heredity and Evolution; Eugenics and Works of a General Character; Genealogy; The Problem of Degeneracy; Alleged Increase of Insanity; Notorious Families; The Heredity of Human Traits; Heredity of Human Defect (Inheritance of Feeble-Mindedness, Inheritance of Epilepsy, Inheritance of Insanity, Inheritance of Deafness, the Hereditary Factor in Tuberculosis); Alcohol in Relation to Heredity; Lead Poisoning; Blastophthoria; Racial Influence of Venereal Disease; The Hereditary Factor in Crime; The Hereditary Factor in Delinquency, Prostitution, Pauperism, and Vagrancy (Delinquency, Prostitution, Pauperism and Vagrancy); The Inheritance of Mental Ability; The Alleged Relation of Genius to Insanity and Other Abnormalities; Race; The Birth-rate; Neo-Malthusianism—Birth Control; Natural Selection in Man; Selective Effect of Infant Mortality; Selective Influence of War; Sexual Selection in Man; Urban Selection and the Influence of Industrial Development on Racial Heredity; The Racial Influence of Religion; Immigration and Emigration as Related to Racial Changes; Consanguinity; Race Mixture and the Intermarriage of Different Stocks; Determination of Sex; The Sex Ratio; The Influence of Age of Parents on Offspring; The Influence of Order of Birth on Offspring; Negative Eugenics, Sterilisation, Segregation. These are set out in full in order that those interested in one or other of the subjects listed may realise that this bibliography is comprehensive and is likely to supply the needs of workers in widely separated fields.

THOUGHT-READING MADE EASY.

THE current number of the *Skandinav. Arch. f. Physiologie* (1924, xlv., 74) contains a paper by Jarl Kohler and Curt Roos on an interesting psycho-physiological phenomenon which, as the authors suggest, is being used by professional thought-readers in their performances. As the result of attending such a thought-reading séance in which the thought-reader had to guess a page in a book which a member of the audience—whom we will call the medium—had selected and of which he was thinking, the authors suspected that a slight involuntary change in the respiratory movements betrayed the thoughts of the medium. They therefore carried out the following experiment. A Marey tambour was fixed to a person so that the respiratory movements could be registered on a drum behind a screen. The person, who was not aware of the object of the tambour, was then asked to think of a figure between 1 and 100 and to concentrate his mind on it. The "thought-reader" then began to count slowly aloud beginning with 1. As soon as he reached the figure of which the "medium" was thinking the "medium" made a number of deep inspirations, which are clearly shown in the records accompanying the paper. Of 12 persons who served as a medium only one was a failure. One made such a deep inspiration when the number was reached that the membrane covering the tambour burst.

THE HEALING ART AMONG THE ANCIENTS.

THAT the practice of medicine and surgery reached a relatively high state of development in ancient Egypt we have abundant proof, both in the records left by the Egyptians themselves and in the references made to Egyptian skill in healing by the later Greek and Roman historians and poets. When the Greeks penetrated to Egypt in the seventh century B.C., Egyptian medicine had probably passed its zenith which some archæologists date as early as 2000 B.C. The history of ancient Egyptian surgery forms the subject of an interesting article by Mr. H. B. Roderick in the Lent number of the *Cambridge University Medical Society Magazine*, where the author gives several quotations from the well-known "Ebers Papyrus," the most ancient complete book in existence, which is held to belong to the fifteenth century B.C., and from which most of our knowledge of ancient medical lore is derived. The papyrus begins with a number of incantations against disease and then proceeds to enumerate a large number of diseases in detail with about 700 different remedies for the same. Thus a favourite Egyptian pomade for baldness consisted of equal parts of the fat of the lion, hippopotamus, crocodile, goose, serpent, and ibex. Another consisted of equal parts of writing ink and cerebro-spinal fluid. A large proportion of the diseases known to modern medical science are carefully classified and their symptoms minutely described. Here we find some approach to the accurate clinical pictures of Hippocrates, and many have supposed on this slender evidence that the Father of Medicine was indebted to Egypt for much of his knowledge. Mr. Roderick does not hold this view, for Greek medicine and particularly surgery even at the time of the Trojan War, was entirely free from priestly domination, whereas later Egyptian medicine was certainly in the hands of the priests. As it is known that the Egyptians practised embalming from about 2500 B.C., it can be inferred that this process necessitated some knowledge of anatomy, and although this was rudimentary in character, records show that the Egyptians reached a degree of knowledge and skill in surgery well in advance of that reached by any of their contemporaries. Their teaching was, however, essentially non-progressive in character, and this characteristic is also seen in the Assyrian medical texts, so faithfully compiled[1] by Mr. R. Campbell Thompson, found in the royal library of Ashurbanipal which belong to a much later date. At the time of Galen Egyptian medical writings had fallen into disrepute, but it can be said that Egypt at least exercised a powerful influence through the channels of Judah and Greece on the development of mankind.

CAR-PROUD.

A "Standard" Owner is naturally proud of his car — as is his wife of her house. He rejoices in its appearance; revels in its excellences; loves to keep it in tune; and drives it with deep pleasure.

There is no car so easy to keep up to pitch. It is so responsive in its work; so complete in detail. It looks —and is—so good. Yet its price and its running costs are small.

The Perfect Car for Professional men

PRICES

14/40 h.p. COUPÉ,
£795
(Including Four-wheel Brakes)

Other Sunbeam Models
from
£570 to **£1,625**

NO car is more suitable for the professional man than a well-designed coupé—especially in this fickle English climate. When closed neither wind, rain nor cold can penetrate : with the head folded back it has all the advantages of an open car.

The 14/40 h.p. Sunbeam Coupé model is so well designed and built that it fully equals the wonderful chassis to which it is fitted. In the chassis such points as the quiet running, overhead valve engine, cantilever rear springing, and Sunbeam four-wheel brakes, operated from one pedal, make this car a real pleasure to drive. Through the traffic of towns or over country roads the 14/40 h.p. Sunbeam gives nothing but satisfaction—and to a degree unequalled by any other medium-powered car of to-day.

A trial run will gladly be arranged on request.

Peptonised Beef Jelly

(Benger) *An agreeable & highly-nourishing Invalid Delicacy.*

For those numerous cases in which solid nourishment cannot be safely prescribed, a palatable and nutritious food can be found in Benger's Peptonised Beef Jelly.

This preparation combines in an unusual degree the qualities of assimilability and high-nutritive content. It is superior to "Beef tea," as the meat itself is made soluble by the action of digestive enzymes.

The Jelly can be served either cold with biscuits, or dissolved in hot water as a soup-beverage. It is sold in hermetically sealed glass jars, ready for immediate use. Price **2/-** and **3/-** each.

Peptonised Chicken Jelly

(Benger) A pleasant change to the Beef Jelly is provided by Benger's Peptonised Chicken Jelly, made on the same principle and being similarly easy of preparation.

NOTE :—Benger's Beef Jelly and Chicken Jelly are entirely free from preservatives.

BENGER'S Food
Trade Mark.

The 'Allenburys' PASTILLES

Glycerine and Black Currant Pastilles

Delicate in flavour. *Efficient in use.*

They are manufactured from pure glycerine and the fresh juice of choice ripe black currants by a special process which conserves the full value and flavour of the fruit. The 'Allenburys' Glycerine and Black Currant Pastilles have a demulcent and mildly astringent effect, most useful in allaying simple irritations of the throat. They dissolve slowly and uniformly, and have a delicious and slightly acidulous flavour.

Supplied in metal boxes containing 2 ozs., 4 ozs., 8 ozs. and 1 lb. respectively.

The 'Allenburys' Medicated Pastilles

may be relied upon to present the accurate amounts of the active ingredients and to be thoroughly effective in use. They dissolve slowly and uniformly, ensuring a thorough suffusion of the medicament over the mucous membrane. 81 varieties of the 'Allenburys' Medicated Pastilles are manufactured.

Descriptive Booklet and Price List sent on request to members of the Medical Profession.

Packed in original tin boxes containing 3 ozs., 8 ozs., and 1 lb. respectively.

TRADE MARK 'TABLOID' BRAND
TRADE 'EMPIRIN' MARK COMPOUND

Supplied to the Medical Profession, in bottles of 25 and 100 at 1/3 and 3/9 per bottle

In order to distinguish the exceptionally pure acetylsalicylic acid manufactured at the 'Wellcome' Chemical Works, Dartford, England, the trade mark word 'EMPIRIN' is employed.

The use of this word has further advantages when it is undesirable for the patient to see the word Aspirin on a prescription.

'TABLOID' 'EMPIRIN' COMPOUND has a very wide application in medicine, because it combines the therapeutic actions of pure aspirin, phenacetin and caffeine.

℞

'Empirin' (Acetylsalicylic Acid)	gr. 3-1/2	(0·227 gm.)
Phenacetini,	gr. 2-1/2	(0·162 gm.)

THE MOABITE STONE: ONE OF THE VERY FEW CONTEMPORARY DOCUMENTS OF HEBREW HISTORY.—This stele of black basalt was erected by Mesha, King of Moab, to commemorate his victories over Israel. Moab and Israel were kinsfolk, speaking dialects of the same language. They may have migrated together from the Syro-Arabian desert, but the Moabites, manifesting in this a pioneer spirit among the Hebrews, abandoned the nomad life much earlier than did the Israelites; they settled down to cultivate the sunny uplands south-east of the Dead Sea. After the Exodus, Israel attacked Moab and reduced it to a state of vassalage. Mesha tells, in this stele, how he threw off the Israelite yoke; "I am Mesha.... King of Moab. My father reigned over Moab 30 years and I reigned after my father.... Omri King of Israel oppressed Moab many days and his son succeeded him; and he also said, I will afflict Moab.... But I saw my desire upon him and Israel perished utterly for ever...." This monument contains what is probably the oldest dated Semitic inscription. The characters resemble those of the old Phœnician alphabet; the language (Moabite) presents only dialectical differences from that of the Old Testament; the vocabulary is identical with that of Hebrew. As the oldest monument of Hebrew history, the Moabite stone possesses unique interest. No Israelite manuscript exists, the extant MSS. of the Old Testament having all been written during our era.

Recognised by Medical Men for nearly a century as a marvellous stomachic without an equal in the treatment of cases of Gastric Trouble, Fevers, Impaired Digestion, Nervous Prostration and similar diseases.

MEAT JUICE.

Described by "The Lancet" as "a powerful, nourishing, and stimulating fluid." Rich in uncoagulated proteid, extractives and salts derived from the fresh muscle juices of the finest British Beef.

BRITISH MADE and prepared at the Dietetic Laboratories of

BRAND & CO., LTD., MAYFAIR WORKS, VAUXHALL, LONDON, S.W. 8.

SULFARSENOL.

THE ARSENOBENZENE OF CHOICE IN THE TREATMENT OF SYPHILIS.

(In use in the Civil and Military Hospitals in France.) Of all forms of Arsenobenzene **SULFARSENOL** is:

THE LEAST DANGEROUS because it is free from arsenoxide; because it is from 2 to 5 times less toxic than the other Arsenobenzenes.

THE MOST CONVENIENT because, being freely soluble, it may be injected intravenously, intramuscularly, or subcutaneously with equal satisfaction and without a special menstruum.

THE MOST EFFICACIOUS because the variety of its modes of administration permits of its application to the exigencies of each particular case, and renders possible the intensive treatment by cumulative doses which secures a therapeutic effect as rapid as it is thorough and permanent.

N.B.—**SULFARSENOL** has a specific action on the acute complications of Gonorrhœa; relief follows the first injection (18-24 centigr.), and subsidence without relapse in a few days.

The Public Health Committee invite applications from qualified Medical Men for the position of Third Assistant Medical Officer in the above Institution.

Every applicant must be a registered Medical Practitioner, under forty years of age, and unmarried.

Preference will be given to applicants with previous Hospital experience. A knowledge in Bacteriological methods is desirable.

Salary £400 per annum, which includes emoluments (board, lodgings, and laundry) valued at £91 13s. per annum, with bonus in addition, which at present amounts to £83 8s. per annum. The commencing cash remuneration is therefore £391 15s.

Every application, stating fully the training, qualifications, and experience of the candidate and his age, with copies of three recent testimonials, and endorsed on the envelope "Medical Officer, Baguley Sanatorium," must be addressed to the Medical Officer of Health, Civic Buildings, 1, Mount-street, Manchester, only, and not to members of the Committee or Council, not later than Saturday, the 12th April, 1924.

The gentleman appointed will be required to contribute to the Corporation Superannuation Fund and to execute the deed of service. Canvassing in any form, oral or written, direct or indirect, is prohibited. P. M. HEATH, Town Clerk.

Town Hall, Manchester, 24th March, 1924.

St. Chad's Hospital, Birmingham.

FOR PAYING PATIENTS. 100 Beds.

RESIDENT MEDICAL OFFICER required (Male or Female). This post offers exceptional educational advantages. The Medical Staff consists of thirty Consulting Specialists in all branches of Medicine. Salary £100 per annum, with furnished apartments, board (excepting stimulants), and laundry.

Candidates must be fully qualified and registered, and have previously held Resident post.

Applications (marked R.M.O.), with full particulars of experience, age, &c., together with copies of recent testimonials, should be sent to the undersigned not later than April 10th, 1924.

DAVID J. RICHARDS, House Governor.

University of Dublin.

TRINITY COLLEGE.

On May 21st, 1924, the Council will proceed to nominate a Whole-time PROFESSOR OF PATHOLOGY, who will be Director of the Departments of Pathology and Bacteriology, to take up his work on October 1st, 1924. Fixed salary £800 a year, plus certain fees. His tenure will be for five years and he will be eligible for re-election. Candidates should send twenty-five copies of not more than five testimonials so that they reach the Dean of the School of Physic, Trinity College, Dublin on or before 1st May, 1924. For further information apply to the Dean of the School of Physic as above.

Western Australia.—Applications are

invited by the Agent-General for Western Australia from duly qualified Medical Men for the position of BACTERIOLOGIST and PATHOLOGIST, Medical and Health Department of Western Australia. Applicants must be fully qualified Practitioners, experienced in and competent to carry out the routine work of a Laboratory, performing all branches of Clinical and Public Health, Bacteriology and Pathology. Commencing salary £708 per annum, rising to £804. Salary to commence from date of arrival in Western Australia. Transport allowance of £200 for married man and £100 for single man. Should the successful applicant voluntarily relinquish the position before the expiration of two years from the date of his appointment, he will be called upon to refund the amount of the transport allowance. Applications, which should be endorsed "Pathologist," must reach the Agent-General for Western Australia, Savoy House, 115–116, Strand, London, W.C. 2, not later than the 12th April, 1924.

PRACTICES AND PARTNERSHIPS FOR SALE.

1. LONDON.—Riverside Suburb. Old-established good-class non-dispensing PRACTICE. Steady average income of over £1800. Fees 5s. to 1 guinea. About 12 cases of Midwifery a year at 5 to 10 guineas. Excellent detached house, with good garden; rent £130. Lease 21 years. Very efficient introduction to suit purchaser's wishes. Premium £3000.

2. ESSEX.—Market Town, within 20 miles of London. Old-established General PRACTICE, comprising all classes of patients, and held by the Vendor many years. Steady average income of about £1375. No appointments. Panel of 500. Advice and medicine 3s. 6d.; visits 5s., 10s., to £1 1s. About 20 Midwifery cases a year at 4 to 8 guineas. Very convenient corner house with large garden; rent £156. Premium £2000, payable part by arrangement.

3. WEST LONDON.—Old-established Mixed General PRACTICE. Income for the last year, approximately, £3000, including panel of 2000. Advice and medicine 2s. upwards; visits 3s. 6d., 5s. About 6 Midwifery cases a year at from 2 to 10 guineas. Ten-roomed house, with small garden, on lease; rent £100. Partnership introduction for 12 months or longer if desired. Premium £4000.

4. CANADIAN COAST TOWN.—Old-established Middle-class PRACTICE, held by Vendor 30 years. Income for the last 12 months £1650; average for the last ten years £1350. No appointments. Nearest opposition 10 miles. Fees: Consultations 1 dollar, medicine 1 dollar extra; visits 2 to 8 dollars. Not much Midwifery, fees 15 to 35 dollars. House is Vendor's own property, and contains 2 reception-rooms, professional rooms, 5 bedrooms, bathroom, &c.; central heating, electric light, &c.; small garden. Trout and salmon fishing, shooting. Premium for house and practice £3500, payable £2000 cash and a mortgage for the balance on the house.

5. DERBYSHIRE.—Hospital Town. Old-established PRACTICE, held 13 years by present Incumbent, who is relinquishing on account of ill-health. Cash receipts for the past 3 years average £3000 per annum, including about £1500 from panel. Fees 3s. 6d. to £1 1s. About 50 cases of Midwifery a year at 2 to 5 guineas. Centrally situated house (2 reception-rooms, consulting- and waiting-rooms, 4 bedrooms, bathroom, &c.) on lease at £100 a year. Premium 1½ years' purchase. Good scope for surgery, and Vendor is on the Staff of the Hospital.

6. NORFOLK.—Unopposed Country PRACTICE. Very old-established, and situated in a very pretty part of the County. Practice is for immediate Disposal owing to the ill-health of the Vendor. Receipts for the past three years average £1500 per annum, including appointments and panel of about 1000. Very little Midwifery. Good house with ample accommodation, small garden; rent £54. Premium to prompt purchaser £1450. Sport of all kinds; tennis club, &c. Efficient introduction given.

7. KENT.—Large Town (within 50 miles of London).—PARTNERSHIP.—A Half Share in an old-established Practice producing an average of over £3800. No panel and no appointments. Surgery fees 2s. and 2s. 6d.; visits 3s. and 3s. 6d.; very little Midwifery, 2½ guineas. Night work extremely light. House on lease, with 2 reception-rooms, 6 bedrooms, bathroom, &c., small garden; rent £60. Premium 1½ years, payable chiefly by instalments.

8. SOUTH-WEST OF ENGLAND.—Large Town. Very sound Middle- and Working-class PRACTICE, held nearly 25 years by present Incumbent, who is relinquishing on account of ill-health. Average cash receipts over £1200 a year, including several small appointments and a panel of over 1300. Visits 3s. 6d. to 10s. 6d. Midwifery from £3 3s.; about 30 cases yearly. Very good house, specially built for a Doctor, contains 2 reception-rooms, waiting-room, consulting-room, surgery with separate entrance, 5 bedrooms, &c.; garden. Premium £1800.

9. PARTNERSHIP.—A Third Share is offered in an old-established General Practice, situated in a Residential Suburb of South-East London. Income for the immediate past year, approximately £2200. Practice offers large scope with the aid of a suitable Partner. No appointments. Panel of 700. Fees from 3s. 6d. upwards. A few Midwifery cases from £3 3s.; choice of houses or suitable rooms can be secured. Premium 2 years' purchase. Cambridge Graduate preferred.

10. PARTNERSHIP.—Kent.—A Half Share of an old-established first-class, unopposed Country Practice, amidst pretty surroundings. Worth about £1600 per annum, including panel about £450 and union and vaccination appointment £50. A number of country houses, farmers, shopkeepers, &c. Suitable arrangements can be made as regards a house. Sport of all kinds, cricket, tennis, &c., hunting. Premium for share 2 years' purchase. Excellent scope.

11. INLAND HEALTH RESORT.—In a very pleasant Town (resident population 1400, which is considerably augmented by visitors during the season) amidst beautiful scenery, an old-established practically unopposed PRACTICE is for Disposal in consequence of the ill-health of Vendor's wife. It is estimated to be worth nearly £1800 a year, including appointments £50 and 500 panel patients. Visits up to £1 1s. Practically no Midwifery; fees 3 to 5 guineas. Excellent residence, standing in its own grounds of ¾ of an acre, with very ample accommodation. Vendor's freehold. Price £3000, of which £2500 can remain on mortgage at 4 per cent. Premium for Practice £3000. The practice offers exceptional future prospects. Tennis, golf, hunting, shooting, &c.

12. SUITABLE FOR TWO LADY DOCTORS.—Well-established and flourishing Middle- and Working-class PRACTICE, situated in populous neighbourhood in East London. Income over £1150, with panel of 1300. Surgery fees 2s. 6d.; visits 3s. 6d. upwards. No Midwifery. Small house will be let or sold. Premium £1750. Large scope for increase.

13. OUTLYING SUBURB OF LONDON (SOUTH).—Old-established, good Middle-class PRACTICE, doing at present at the rate of £1200 a year. Vendor has no panel, but there is very large scope in this direction. Visits 5s. upwards. Very little Midwifery, and nothing under £5 5s. Exceptionally attractive residence with good accommodation, garden, &c. It is the Vendor's freehold; price £2000, a good part of which can remain on mortgage. Premium for practice £1500.

14. FAR EAST.—Three MEDICAL OFFICERS required on Railways. Salary about £600 a year, increasing annually. Three years' engagement. First-class passage out and home. Age 25-30. Scotchmen preferred. Personal application if possible to Bovril Medical Agency.

Profits accruing to Bovril, Ltd., from the Agency will be allocated among recognised Medical Charities.

Full Schedule of Terms and Conditions will be forwarded on application.
